POLISH MARITIME RESEARCH is a scientific journal of worldwide circulation. The journal appears as a quarterly four times a year. The first issue of it was published in September 1994. Its main aim is to present original, innovative scientific ideas and Research & Development achievements in the field of:

**Engineering, Computing & Technology, Mechanical Engineering,**

which could find applications in the broad domain of maritime economy. Hence there are published papers which concern methods of the designing, manufacturing and operating processes of such technical objects and devices as: ships, port equipment, ocean engineering units, underwater vehicles and equipment as well as harbour facilities, with accounting for marine environment protection. The Editors of POLISH MARITIME RESEARCH make also efforts to present problems dealing with education of engineers and scientific and teaching personnel. As a rule, the basic papers are supplemented by information on conferences, important scientific events as well as cooperation in carrying out international scientific research projects.

### Scientific Board

Chairman: Prof. **Jerzy Girtler** - Gdańsk University of Technology, Poland  
Vice-chairman: Prof. **Antoni Jaroszko** - Institute of Aeronautics, Poland

Multi-objective optimization of high speed vehicle-passenger catamaran by genetic algorithm

Part II
Analysis of the results

Zbigniew Sekulski, Ph. D.
West Pomeranian University of Technology in Szczecin

ABSTRACT

Real ship structural design problems are usually characterized by presence of many conflicting objectives. Simultaneously, a complete definition of the optimum structural design requires a formulation of size-topology-shape-material optimization task unifying the optimization problems from the four areas and giving an effective solution of the problem. Any significant progress towards solving the problem has not been obtained so far. An objective of the present paper was to develop an evolutionary algorithm for multi-objective optimization of the structural elements of large spatial sections of ships. Selected elements of the multi-criteria optimization theory have been presented in detail. Methods for solution of the multi-criteria optimization problems have been discussed with the focus on the evolutionary optimization algorithms. In the paper an evolutionary algorithm where selection takes place based on the aggregated objective function combined with domination attributes as well as distance to the asymptotic solution, is proposed and applied to solve the problem of optimizing structural elements with respect to their weight and surface area for a high-speed vehicle-passenger catamaran structure, with taking into account several design variables such as plate thickness, scantlings of longitudinal stiffeners and transverse frames, and spacing between longitudinal and transversal members. Details of the computational models were kept at the level typical for conceptual design stage. Scantlings were analyzed by using the selected classification society rules. The results of numerical experiments with the use of the developed algorithm are presented. They show that the proposed genetic algorithm may be considered an efficient tool for multi-objective optimization of ship structures.

The paper has been published in the three parts: Part I: Theoretical background on evolutionary multi-objective optimization, Part II: Computational simulations, and Part III: Analysis of the results.

Keywords: ship structure; multi-objective optimization; evolutionary algorithm; genetic algorithm; Pareto domination, set of non-dominated solutions

ANALYSIS OF THE RESULTS AND CONCLUSIONS DRAWN FROM THE COMPUTATIONAL SIMULATIONS

Three series of the computer simulations, signed sym1, sym2 and sym3, confirmed effectiveness of the developed computational algorithm and computer code for solution of the formulated problem of ship structure topology-size multi-objective optimization. As a result of the calculations an approximation of the Pareto-optimum set containing, in each simulation, from a few to more than ten non-dominated solutions, was found. The obtained results do not allow to unequivocally conclude which of the examined factors: (1) objective function aggregation strategies, (2) domination attributes included into selection process, and (3) distance to asymptotic solution included into selection process, is most advantageous.

In the case of studying the influence of optimization criteria aggregation strategy, visual assessment of the shape of the obtained approximations of the Pareto-optimum set suggests an advantage of the strategy with random values of the weight coefficients \( w \) (sym1-2) and the least effectiveness of the strategy with fixed values of the weight coefficients \( w \) (sym1-1).

The effectiveness of the strategy with random selection of single optimization criteria in the selection process (sym1-3) is intermediate. In the case of the constrained problems it also turns out that the components of the penalty functions introduce a random contribution to the fitness function thus causing the strategy with the fixed weight coefficients \( w \) to be practically
a strategy similar to the two others and it also allows to find approximation of the Pareto-optimum set with the adequate accuracy.

From the found sets of the compromise solutions a user can select, in the next stage, one or a few solutions by applying additional premises which are not included in the optimization model. He can also select suggested non-dominated solutions the closest to the asymptotic solutions $f$:

$$f_{\text{sym}1-1} = [1086.28 \ 7422.10]^T \cdot [\text{kN} \ \text{m}^2] \Rightarrow$$

$$f_{1,\text{sym}1-1}(x) = 1086.28 \ \text{kN}, \ f_{2,\text{sym}1-1}(x) = 7422.10 \ \text{m}^2$$

$$f_{\text{sym}1-2} = [1113.65 \ 7361.45]^T \cdot [\text{kN} \ \text{m}^2] \Rightarrow$$

$$f_{1,\text{sym}1-2}(x) = 1113.65 \ \text{kN}, \ f_{2,\text{sym}1-2}(x) = 7361.45 \ \text{m}^2$$

$$f_{\text{sym}1-3} = [1153.68 \ 7381.57]^T \cdot [\text{kN} \ \text{m}^2] \Rightarrow$$

$$f_{1,\text{sym}1-3}(x) = 1153.68 \ \text{kN}, \ f_{2,\text{sym}1-3}(x) = 7381.57 \ \text{m}^2$$

Since this way three solutions are obtained, the next question is which of them can be recommended as the best\(^1\). Here the following procedure is suggested by this author: non-dominated solution sets obtained in subsequent simulations can be merged into a temporary solution set presented in Fig. 39a. In this set only a part of solutions is non-dominated ones, Fig. 39b. In the set of 15 non-dominated solutions obtained by using the results of three simulations, a distance of each of them from the asymptotic objective in normalized objective space, can be determined, Fig. 39c. The least distance equal to 1.082, was obtained for the solution $f_1(x) = 1113.65 \ \text{kN}$ and $f_2(x) = 7361.45 \ \text{m}^2$ found in the simulation sym1-2 (random values of the weight coefficients $w_1$ and $w_2$ in the range $[0, 1]$). The solution can be recommended as a single solution of the formulated problem of multi-objective optimization.

Effectiveness of the three examined multi-objective optimization strategies which use optimization criteria values and functions representing violation degree of constraints,

---

\(^1\) Let us remember that in the multi-objective optimization there is not the single best solution of the problem and the formulated recommendation should be treated as a subjective choice by a person taking decision.
can be roughly evaluated also by assuming that the number of solutions produced by a given algorithm, that is a part of set of non-dominated solutions obtained on the basis of results produced by all algorithms, Fig. 39, is a measure of algorithm effectiveness. In the examined example the particular simulations: sym1-1, sym1-2 and sym1-3 have brought respectively 6, 6 and 3 non-dominated solutions into set of non-dominated solutions. On this basis a conclusion may be suggested that the strategies of fixed values of the optimization criteria weight coefficients $w_1 = w_2 = 0.5$ and random values of the weight coefficients $w_1$ and $w_2$ in the range $[0, 1]$ show similar effectiveness whereas the strategy of random values of the weight coefficients $w_1$ and $w_2$ equal to 0 or 1 proved to be the least effective. The issue of examining the effectiveness of multi-objective evolutionary algorithm is very relevant and not fully solved hence it requires a separate research which exceeds however content of this case study.

The conducted analysis of computer simulation results of the problem of ship structure multi-objective optimization in question allows to state that in the studied cases the most effective strategies were the following: (1) that with random values of the weight coefficients $w_1$ and $w_2$ in the range $[0, 1]$, and that with fixed values of the optimization criteria weight coefficients $w_1 = w_2 = 0.5$. Less effective was the strategy with random values of the weight coefficients $w_1$ and $w_2$ equal to 0 or 1.

The recommended non-dominated solution was obtained for the values of design variables specified in Tab. 8. The corresponding dimensions of the ship cross-section are given in Fig. 40.

From the study of influence of dominance attributes and distance from asymptotic solution on the effectiveness of the algorithms of sym2-1, sym2-2 and sym2-3, also satisfactory results were achieved as follows:

$$f_{sym2-1} = [1105.95 \, 7345.11]^T \, [kN \, m^2] \Rightarrow f_{sym2-1} (x) = 1105.95 \, kN, f_{sym2-1} (x) = 7345.11 \, m^2$$

$$f_{sym2-2} = [1192.04 \, 7327.41]^T \, [kN \, m^2] \Rightarrow f_{sym2-2} (x) = 1192.04 \, kN, f_{sym2-2} (x) = 7327.41 \, m^2$$

$$f_{sym2-3} = [1060.03 \, 7485.93]^T \, [kN \, m^2] \Rightarrow f_{sym2-3} (x) = 1060.03 \, kN, f_{sym2-3} (x) = 7485.93 \, m^2$$

In the case of necessity to identify a single solution from a series of simulations one can apply the earlier described procedure of aggregation of set of non-dominated solutions obtained in particular simulations and identify the non-dominated solution nearest the asymptotic solution.

The performed calculation investigations have positively verified the effectiveness of the combined fitness multi-objective evolutionary algorithm developed by this author, as well as the calculation tool built for solving the unified ship structure topology-size multi-objective optimization problem. Particular computer simulations have produced a dozen or somewhat more of non-dominated solutions which constitute the set of trade-off solutions from among which decision makers may choose one or more of them for further development. The algorithm developed as a part of the underlying work allows also to pinpoint a single variant closest to the asymptotic solution which may be proposed as a single solution of the multi-objective optimization problem.

Fig. 41 presents the comprehensive results of the multi-objective optimization of the ship hull structure: (1) general arrangement and main particulars of an example ship, (2) optimization criteria, (3) simulation main parameters and control variables, (4) values of optimization criteria for the obtained non-dominated variants, (5) values of optimization criteria for the variant closest to the asymptotic solution, and (6) structural dimensions and scantlings for this variant.

PERFORMANCE ASSESSMENT OF THE DEVELOPED MULTI-OBJECTIVE OPTIMIZATION ALGORITHM

The question should be answered if the proposed combined fitness multi-objective evolutionary algorithm (Eq. 28) is more efficient than the evolutionary algorithms used in the process of selection of only optimization criteria (in the form of scalar substitute optimization criteria) and functions representing the degree of constraint violation (Eq. 8). Unfortunately the answer cannot be simple and unequivocal.

In practical problems the ship structural multi-objective optimization which produces a set of Pareto-optimum solutions may be very computation time-consuming or even impossible to be performed. In the cases the evolutionary algorithms of multi-objective optimization do not guarantee identification of Pareto-optimum compromises but can help identifying a satisfactory approximation, i.e. a set of solutions hoped to be not too far distant from searched front of optimum solutions (in the sense of Pareto). However in this case methods are necessary to evaluate how good produced solutions of formulated problems are. And, this leads to the question: how to compare effectiveness of different algorithms? In the context of the presented work the question may be formulated as follows: how to compare effectiveness of the studied evolutionary multi-objective optimization of ship hull structure, assumed for different evaluation strategies of fitness function.

In the case of the evolutionary algorithms of multi-objective optimization, statistical in their nature, evaluation of obtained results and comparison of effectiveness of optimization algorithms implementing different strategies is a very difficult task, arousing much controversy and misunderstanding. Whereas visual and qualitative comparison of the sets approximating Pareto front is commonly used for deduction of quality of evolutionary multi-objective optimization, in the case of quantitative methods the searching of proper standards are just under way [Knowles, Thiele, Zitzler (2006)].

In the case of single-objective optimization the selection of quality measure is obvious and simple: optimization criterion. The quantity is unequivocally defined, optimization criterion value calculated for every test solution, and smaller or greater depending on the task, which corresponds to better solution. In the case of multi-objective optimization it is not clear what „better“ means: is it that located closer to the front of optimum solutions, covering a wider range of solution characteristics, or something else? And, it should be realized that the front of Pareto-optimum solutions is unknown. That is why it is difficult to define proper quality measure for approximations of an unknown front of Pareto-optimum solutions. Therefore for comparing and evaluating results of qualitative evaluation of multi-objective evolutionary algorithms, graphical presentation of obtained non-dominated solutions has been first of all used until recently [Veldhuizen (1999)].

In recent years in this field a certain progress has been made and several papers concerning the quantitative comparing of different approximations of Pareto-optimum set can be found. The most popular is the unary quality measure, i.e. that which attributes, to every single approximation set, one numerical value which reflects a specified quality aspect [Veldhuizen, Lamont (2000)], [Zitzler, Thiele, Laumanns, Fonseca, Grunert da Fonseca (2002)]. To increase the deducing strength the unary quality measures are usually used jointly, to cope of taking into account different aspects of the notion of “quality”. Other methods are based on binary quality measures which assign numerical values to pairs of solutions, [Zitzler, Thiele (1998)], [Hansen, Jaszkiewicz (1998)].

Third group of evaluation methods, completely different in conceptual respect, is the method of attainment function,
High-speed vehicle-passenger catamaran,
Auto Express 82 type

Main particulars:
- length overall, \( L = 90.0 \text{ m} \),
- breadth, \( B = 23.0 \text{ m} \),
- maximum depth, \( H = 11.7 \text{ m} \),
- length of midship block-section subject to optimisation, 17.0 m.

Properties of structural material:
- aluminium alloys,
- 5083-H111 alloy for plates \((R_{0.2} = 125 \text{ N/mm}^2)\),
- 6082-T6 alloy for bulb extrusions \((R_{0.2} = 250 \text{ N/mm}^2)\).

Multi-objective topology and size optimisation of ship structure by evolutionary algorithm with combined fitness function, CFMOEA, based on genetic algorithm

Combined fitness function:

\[
f(x) = w_1 f_1(x) + w_2 f_2(x) + w_{\text{rank}} \cdot \text{rank}(x) + w_{\text{count}} \cdot \text{count}(x) + w_{\text{distance}} \cdot \text{distance}(x) + \sum_{k=1}^{n} (w_k \cdot \text{penalty}_k(x))
\]

Optimization criteria:
- structural weight \( f_1(x) \), kN,
- surface area for cleaning and painting \( f_2(x) \), m².

Parameters of CFMOEA simulation:
- sym2-1,
- number of individuals \( n_i = 5,000 \),
- number of generations \( n_g = 10,000 \),
- \( w_1 = w_2 = 0.0 \),
- \( w_{\text{rank}} = 3.0 \), \( w_{\text{count}} = 0.0 \), \( w_{\text{distance}} = 0.0 \).

The best (recommended) solution:
- structural weight \( f_1(x_4) = 1106 \text{ kN} \),
- surface area \( f_2(x_4) = 7345 \text{ m}^2 \).

Midship section structural arrangements and scantlings of the best solution

Fig. 41. Result of the multi-objective evolutionary optimisation of the ship structure with respect to the structural weight \( f_1 \), and surface area of structural members for maintenance (cleaning and painting) \( f_2 \), (sym2-1)
Fig. 41 cont. Result of the multi-objective evolutionary optimization of the ship structure with respect to the structural weight $f_1$ and surface area of structural members for maintenance (cleaning and painting) $f_2$ (sym2-1), which contains: evolution of the highest value of fitness function and the lowest value of non-dominated solution distance from asymptotic one; structure of the set of non-dominated solutions; number of generations in which particular non-dominated solutions were found; detailed structure of the set of non-dominated solutions; structure of the set of non-dominated solutions in normalized objective space.
Let's notice that fulfillment of mentioned algorithm quality aspects can be considered as multi-objective task of algorithm optimization. However, as far as the problem of multi-objective optimization is concerned there are several reasons due to which it is difficult to evaluate obtained results. Firstly, from evolutionary algorithms many solutions are obtained instead of only one, usually as many as possible solutions belonging to the set of non-dominated solutions, approximation set of Pareto-optimum solutions, are aimed at. Secondly, evolutionary algorithms are stochastic, therefore for effectiveness evaluation it is necessary to run many simulations and subject obtained results to statistical analysis; in this case drawn conclusions will also have stochastic characteristics. Thirdly, we may be interested in measuring different aspects of quality; for example, we may be more interested in possessing a robust, but slower, algorithm convergent to Pareto front practically in every case, than in a faster algorithm but convergent to Pareto front only occasionally (in case of specific types of tasks); we also may be interested in evaluating behaviour of evolutionary algorithm in the course of simulation, trying to determine its capability of maintaining diversity and gradual convergence to set of solutions close to Pareto front. This short discussion shows how difficult is to develop effectiveness measures for multi-objective optimization evolutionary algorithms.

The next problem in the discussion is the question: what should be measured? It is very important to determine what kind of results will be subjected to measurement, evaluation and analysis, and to define quality measures according to a task. It is obvious that in the formulating of a good quality measure for multi-objective optimization evolutionary algorithm the following should be considered: [Zitzler, Deb, Thiele (1999)]:

1. the minimizing of distance between approximation of Pareto front, obtained by the algorithm, and a real Pareto-optimum front of solutions, (of course if so is known, what in practice of optimizing engineering objects does not happen),
2. the maximizing of diversity of obtained non-dominated solutions, i.e. the arranging of non-dominated solutions in approximation set over empirical compromise area, as smoothly and homogeneously as possible,

In particular [Zitzler, Thiele, Laumanns, Fonseca, Grunert da Fonseca (2002)] showed that if we have two sets of solutions, a and B, which approximate Pareto-optimum set of solutions, then we cannot elaborate a finite set of quality measures, which can indicate if the approximation a of Pareto-optimum set is better that the approximation B, in every case. Elaborated quality measures may be applied only to specific aspects of the quality concept, therefore the only thing left to deduce is that the approximation a is not worse that the approximation B, which means that either the approximation a is better than the approximation B, or the approximations a and B are incomparable with regard to a specified quality measure. This statement cannot be generalized in a way indicating that the approximation a is always better than the approximation B. So if it is impossible to state in a close and exact quantitative way the supremacy of one approximation set over the other, therefore it is impossible to state the supremacy of one algorithm over the other. Choice of one of them is determined by the efficiency in every specific case it was used.

[Sarker, Coello Coello (2002)]21(48,1814),(952,1849) made a review of propositions they considered the most important and enabling to measure the three above listed aspects of the notion „quality”, subjected to evaluation. They also observed that there is no method that would allow to measure the three aspects with one value only. Unfortunately, attempts to elaborate a single measure for grasping them together have not been successful so far because they concern very different algorithm characteristics. That is why the attempts to reduce them to one measure may lead to misunderstandings. Therefore the using of different quality measures to estimate different aspects of algorithm behaviour seems more proper in practice.

On the basis of visual assessment of approximating sets attained in particular simulations, Fig. 42, it can be stated that the best solutions, i.e. approximation sets, were obtained in the simulations: sym2-1 (w1 = w2 = 0.0, wrank = 3.0, wcount = 0.0, wdistance = 0.0), sym1-2 (w1, w2 are random in the range [0, 1], wrank = 0.0, wcount = 0.0, wdistance = 0.0) and sym2-3 (w1 = 0.0, wcount = 0.0, wdistance = 0.0). Solutions obtained from the simulations are arranged the most uniformly, hence they can be expected to be a good representation of searched Pareto-optimum front. In the case of the remaining simulations: sym1-1 (w1 = w2 = 0.5, wrank = 0.0, wcount = 0.0, wdistance = 0.0), sym1-3 (w1, w2 are random 0 or 1, wrank = 0.0, wcount = 0.0, wdistance = 0.0) and sym2-2 (w1 = 0.0, wrank = 0.0, wcount = 0.0, wdistance = 0.0), the found solutions are arranged less uniformly, hence they represent Pareto-optimum front in a worse manner. Therefore it can be approximately stated that out of six conducted research simulations the following were found more effective: the simulation (1) that took into consideration influence of dominance attribute, i.e. dominance rank, the simulation (2) that took distance of the asymptotic solution into consideration, and the simulation in which the selection process is controlled only by optimization criteria. Less effective were found the simulations (4) and (5) in which selection process was controlled only by optimization criteria, the simulation (6) that took into consideration the influence of dominance attribute, i.e. dominance count. Thus in the group of more effective strategies there were two simulations which use the combined fitness and one simulation which realizes the strategy of random combination of objective function without

---

21 Let's notice that fulfillment of mentioned algorithm quality aspects can be considered as multi-objective task of algorithm optimization (optimizer).
Fig. 42. Specification of the sets of non-dominated solutions obtained during the performed genetic multi-objective optimization simulations of ship structure with respect to the structure weight $f_1$ and the surface area $f_2$: black circles represent non-dominated solutions, red dots represent non-dominated solutions closest to the asymptotic one.
taking into consideration domination attributes. On the basis of such superficial quality analysis can be proposed the statement that the combined fitness multi-objective optimization algorithm can be a more efficient strategy for multi-objective optimization of ship structure than scalarization of objective function strategy, without taking into consideration domination attributes in selection process.

The conducted series of computer simulations confirmed efficiency of the developed computational algorithm and computer program for solving the formulated unified problem of topology and optimization of ship structure dimensions. As a result of the calculations, were elaborated approximations of the set of Pareto-optimum solutions which in particular contain simulations of non-dominated solutions, from several to a dozen or somewhat more in number. The obtained results do not allow to unequivocally determine superiority of any examined strategies of fitness function evaluation. For formulating more detailed quantitative conclusions further systematic statistical studies performed on much larger number of samples, are necessary.

In the case of ship structure optimization the problem of efficiency assessment of elaborated algorithms is additionally complicated by the necessity of formulating many constraints and including them to the fitness function. In the task considered in this publication forty constraints were assumed. The constraint represented in optimization model in the form of proper components of penalty function, \( n_c = 40 \), very strongly limit solution space available for searching; this way they also distort image of influence of the assumed fitness function computing strategies on algorithm convergence and the quality of attained solutions and therefore on the efficiency of the studied algorithms.

From practical point of view it is interesting to notice which of the formulated constraints appears active in optimization process and which does not. In the first case to allocate large computational outlay to control them is justified. In the other case such outlay may appear useless from the point of view of effectiveness of optimization process and in some cases it is possible even to resign from controlling them. In the case of the optimization model used in this work the constraints in the form given by the inequality (21) concerning the required section moduli values of web frames in the three structural regions: side outboard region, bottom region and wet deck region, appeared active. In the case of the remaining constraints dealing first of all with the required thickness values of plates and dimensions of frames, the formulated constraints are satisfied with a large excess.

The final conclusion can be formulated as follows: one cannot formulate a finite number of quantitative measures which allow putting in order the set of Pareto-front approximating sets in relation to the quality, and therefore one cannot formulate objective quality/efficiency measures of the proposed multi-objective optimization evolutionary algorithms. Thus one cannot prove objectively and unequivocally the supremacy of one of the algorithms proposed and discussed in this work or realization strategies of one of them. It depends on a potential user whether he / she would consider the presented concept interesting, elaborate its computer realization and finally verify its efficiency in his / her specific case.

**SUMMARY AND CONCLUSIONS**

The problem of minimization of weight and total surface area of the complete three-dimensional midship block-section of the high-speed catamaran hull was presented and discussed in detail. The strength criteria for checking ship structure were taken from the selected classification rules. The calculation tool for solving the formulated unified problem of the multi-objective optimization of topology and scantlings of the sea-going ship hull structure was developed with the accuracy typical for the preliminary design stage.

The application of the genetic algorithm concept to solve the formulated optimization problem was presented. In the study it was proved that the genetic algorithm allows to include, in the multi-objective optimization model, a large number of design variables of real ship structure. The introducing of constraints related to strength, fabrication and standardization is not difficult and may cover a more representative set of criteria.

The aggregation method was proved effective even in the case of the fixed values of the weight coefficients since in the case of the constrained problem the components of the penalty function introduce a random influence to the fitness function. The method is thus closer to that based on the random weight coefficients of the optimization criteria.

This author has discussed crucial role of Pareto domination relation in process of evolution of feasible solutions for ship structure towards Pareto-front containing non-dominated variants of the ship structure. Using the concept of domination in the set of feasible solutions this author has proposed his own definitions of the concept of domination rank as well as domination count, enabling this way to take into account relation between a feasible variant and other feasible variants. Basing on the ideas the author has proposed an evolutionary algorithm for solving the problem of topology-size multi-objective optimization of hull structure of sea-going ship, which uses, in selection process, the combined fitness function which allows taking into account, in selection process, the following items: (1) optimization criteria, (2) dominance attributes, (3) distance to the asymptotic solution as well as (4) penalty functions for violating assumed constraints. The computational program which makes it possible to perform ship structure multi-objective optimization with an accuracy appropriate for preliminary design stage, was elaborated. By using the tool and elaborated computational model of hull structure, series of computer simulations were conducted for the fast catamaran passenger-vehicle ferry of Auto Express 82 design. The results of the performed computations and subsequent discussion gave reasons for the statement that the elaborated algorithm may be considered an efficient tool for multi-objective optimization of ship structures in the preliminary design stage.

It should be remembered that the developed multi-objective optimization algorithm is based on the random processes therefore the obtained results should be interpreted in the statistical sense. It means that the simulations and their results may appear sometimes not representative. a slight change of the developed models or control parameters may result in a different course of simulation and lead to different results. In this context further systematic studies on algorithm efficiency controlled by a particular component of combined fitness function, are necessary.

Further systematic investigations of effectiveness of the proposed strategies, including repeated computations different to each other only by evolution history, aimed at statistical confirmation of the effectiveness, are deemed necessary.

ABSTRACT

The article presents the results of the research project concerning tip vortex cavitation. This form of cavitation is very important in operation of many types of rotary hydraulic machines, including pumps, turbines and marine propellers. Tip vortex cavitation generates noise, vibration and erosion. It should be eliminated or significantly limited during the design of these types of machines. The objective of the project was to develop an accurate and reliable method for numerical prediction of tip vortex cavitation, which could serve this purpose. The project consisted of the laboratory experiments and numerical calculations. In the laboratory experiments tip vortex cavitation was generated behind a hydrofoil in the cavitation tunnel and the velocity field around the cavitating kernel was measured using the Particle Image Velocimetry method. Measurements were conducted in three cross-sections of the cavitating tip vortex for a number of angles of attack of the hydrofoil and for several values of the cavitation index. In the course of numerical calculations two commercial CFD codes were used: Fluent and CFX. Several available approaches to numerical modeling of tip vortex cavitation were applied and tested, attempting to reproduce the experimental conditions. The results of calculations were compared with the collected experimental data. The most promising computational approach was identified.

Keywords: rotary hydraulic machinery; cavitation; numerical methods; experimental techniques

INTRODUCTION

One of the most important problems in design of different types of rotary hydraulic machines, such as marine propellers, water turbines and pumps is the as accurate as possible prediction of cavitation properties of these machines. Such a prediction enables elimination or significant limitation of the cavitation phenomena at the design stage. Among different types of cavitation, the tip vortex cavitation plays a very important role, because it is responsible for generation of intensive noise and vibration and also often causes erosion of the machinery elements. Development of accurate and reliable method for numerical prediction of tip vortex cavitation is the objective of research described below.

The mechanism of formation of the cavitating tip vortex is shown schematically in Fig. 1. Combination of the inflow velocity to the hydrofoil and intensive rotation of the liquid around the vortex leads to the region of strongly reduced pressure, with minimum at the centre of the vortex just behind the tip of the foil. The complicated contradictory phenomena of concentration and dissipation of vorticity plays an important role in this process. Cavitation nuclei, i.e. micro-bubbles naturally present in the liquid, are pushed by the pressure distribution into the centre of the vortex, where in sufficiently low pressure they undergo rapid growth, leading to formation of the cavitating kernel of the vortex.

Fig. 1. Scheme of formation of the cavitating tip vortex
The accurate determination of the pressure distribution in close vicinity of the tip vortex is the obvious pre-requisite for effective prediction of the tip vortex cavitation. The methods for calculation of the velocity and pressure around a tip vortex were the subject of earlier research published in [1, 2, 3, 6].

The continuation research, presented in this article, consists of the experimental and numerical parts. The purpose of the experimental part is to supply information about the velocity field around the cavitating tip vortex, necessary for development of the numerical methods and data concerning the geometry of the cavitating vortex for experimental verification of the numerical results. In the numerical part of the research project two commercial computer CFD codes were used and several available models of turbulence were tested. The detailed presentation of the experimental and numerical research is included in the following sections of the article.

EXPERIMENTAL MEASUREMENTS OF THE VELOCITY FIELD AROUND THE CAVITATING TIP VORTEX

The experiments were conducted in the cavitation tunnel of the Department of Energy and Industrial Apparatus of the Gdansk University of Technology, shown in Fig. 2. This tunnel has a rectangular measuring section having the dimensions 3.0*0.35*0.45 meters. The maximum flow velocity in the tunnel is 6 meters per second. The velocity measurements around the cavitating tip vortex were performed using the Particle Image Velocimetry method and they were conducted by the team from the Warsaw University of Technology, Faculty of Civil Engineering, Mechanics and Petrochemistry. The PIV equipment set-up is also shown in Fig. 2.

The hydrofoil model used in the experiments was specially designed on the basis of the typical contemporary marine propeller blade geometry, which was developed onto a plane surface (cf. Fig. 3). The span of the hydrofoil was selected equal to 225 mm in order to ensure that the cavitating tip vortex was located approximately in the centre line of the measuring section. The hydrofoil was manufactured of bronze and mounted vertically in the tunnel by means of the mechanism enabling accurate control of the angle of attack.

The PIV measurements were conducted for a number of conditions, resulting from combinations of angle of attack and flow velocity. These conditions are listed in Table 1, together with the locations of three measurement planes. These planes were perpendicular to the tunnel axis and they were located 50, 200 and 300 mm behind the tip of the hydrofoil, in order to visualize the process of development of the cavitating tip vortex. The combination of all conditions listed in Table 1 produced 27 measurements of flow velocity (3 velocities * 3 angles of attack * 3 measuring planes). During the experiments the static pressure in the tunnel was kept constant at 15 [kPa] and the variation in the cavitation index were obtained through changes in the flow velocity. The cavitation index \( \sigma \) is defined according to the formula:

\[
\sigma = \frac{p - p_v}{\frac{1}{2} \rho V^2}
\]

where:
- \( p \) – the static pressure in the tunnel
- \( p_v \) – the critical vapour pressure
- \( \rho \) – the liquid density
- \( V \) – the flow velocity

PIV method enables determination of the velocity vectors on the basis of measurement of displacement of particles between two correlated pictures created by the laser light (cf. Fig. 5) and registered consecutively in a short time interval.
by the camera. In order to provide sufficient number of micro-
particles in the flow, necessary for effective PIV measurements,
the water in the tunnel was seeded with a silver metallic paint.
The deflection of the light beam when crossing the window-
water boundary was taken into account. The results of PIV
measurements were stored in computer files and then filtered
and re-calculated using specialized software.

The scheme of the PIV measuring system is shown in Fig. 4. The
distances of the camera K from the measuring section were kept constant b = 570 mm and c = 668 mm. The distance of
the laser L from the measuring section was constant and equal
to a = 440 mm. The distances of the measuring plane from the
hydrofoil tip were varied: d = 50, 200 and 300. The system
was arranged in such a way that the angle between the laser
light plane and the camera axis was approximately equal to 45
degrees in all measurements.

Fig. 4. Scheme of the measuring system

Fig. 5 shows the laser light in the measuring plane 50 mm
behind the hydrofoil tip during the PIV measurements. Apart
from the PIV measurements the photographic registration of the
cavitating tip vortex was performed. The complete description
of the measurements may be found in [5].

NUMERICAL PREDICTION OF THE
CAVITATING TIP VORTEX

The purpose of the first stage of calculations in the research
project, described in this article, was to test and compare
different CFD programs and different turbulence models
from the point of view of their ability to predict accurately the
geometry of the cavitating kernel of the tip vortex. One flow
condition was selected for this comparison, namely hydrofoil
angle of attack equal to 8 degrees and the velocity of flow
equal to 5.2 m/s. The geometry of the computation domain
taken into account in the CFD calculation is shown in Fig. 6 It
may be seen that quite a large section of the cavitation tunnel,
especially in front of the hydrofoil, was modeled numerically.
The inlet confuser was taken into account in the simulations in
order to obtain the similar velocity distribution upstream the
hydrofoil as in the measurements. Calculations were performed
using two commercial CFD programs: Ansys/Fluent v12 and
Ansys/CFX. In order to demonstrate the practical accuracy of
numerical prediction of the cavitating tip vortex, the authors
of calculations were not familiar with the experimental results
beforehand. They prepared and performed the calculations
using their best experience.

The unstructured computational grid for Fluent is
constructed of about 4.7 million of hexahedral elements. The
mesh was created in Hexpress/Numeca mesh generator. The
density of element distribution is increased near the tunnel walls
in order to keep y+=1. In view of the anticipated presence of the
tip vortex the grid had also significantly increased density in the
region behind the hydrofoil tip – see Fig. 7. In computations
the MUSCL (Monotone Upstream-Centered Schemes for
Conservation Laws) scheme was used and 4 turbulence models
were tested:
- standard k – ε model
- k – ε RNG
- k – ω SST
- Reynolds Stress Model (RSM)

Boundary conditions were set as follows:
- at the inlet plane:
  - mass flow rate 437 kg/s (it corresponds to velocity at
    the test section ~5.2 m/s)
  - total temperature 283 K
  - turbulence intensity 1%
  - turbulent viscosity ratio 10
- at the outlet plane
  - static pressure 15 kPa

Fig. 6. The domain of flow taken into account in CFD calculations

Fig. 7. Discretization of the hydrofoil and the plane behind it used in Fluent
A mixed two-phase model was used in the calculations of the cavitating flow. Cavitation was determined on the basis of Rayleigh-Plesset equation in Zwart-Gerber-Belamri formulation [7]. The gaseous phase was treated as a compressible medium according to the perfect gas model.

Calculations performed using the Ansys/CFX program were performed on the basis of unstructured grid having about 9 million elements, including about 8.2 million tetrahedral elements and about 0.8 million prismatic elements in the boundary layer. Part of this grid located in the vicinity of the hydrofoil is shown in Fig. 8. The gaseous phase was treated as an incompressible medium in case of Ansys/CFX simulations.

In the calculations by CFX the same turbulence models were used as in Fluent case.

The comprehensive description of CFD calculations may be found in [4].

COMPARISON OF THE EXPERIMENTAL AND NUMERICAL RESULTS

Comparison of the registered and calculated geometry of the cavitating tip vortex

The photograph of the cavitating tip vortex in the analyzed flow condition (angle of attack 8 degrees, velocity of flow 5.2 m/s) is shown in Fig. 9, while the results of corresponding CFD calculations are presented in Figs. 10, 11 and 12. The detailed analysis of the figures leads to the following observations:

- there are significant differences between Fluent and CFX predictions, even when using the same turbulence model; these differences may be attributed to the markedly different structure in the computational grid between both programs,
- similarly important differences may be found in predictions by each of the programs (Fluent or CFX) while using different turbulence models,
- CFX results are much less dependent of the turbulence model than the Fluent ones,
- the differences in performance between Fluent and CFX for the same turbulence models result most likely from the different structures of the computational grids and numerical schemes implemented in the solvers
- k-ε RNG turbulence model seems to be the best suited for prediction of tip vortex cavitation and it performs equally well both in Fluent and CFX,
- standard k-ε turbulence model in Fluent case gives the shortest cavitating zone what is highly related to the dissipative nature of this model
- CFX results for standard k-ε and SST turbulence model give surprisingly the same results
- both programs predicted some sheet cavitation at the root of the hydrofoil which was not observed in the experiment.
perpendicular to the axis of the cavitating vortex) and they are grouped together according to the distance of this plane from the hydrofoil tip. Figs. 13, 14, 15, 16 show the results for 50 mm distance, Figs 17, 18, 19, 20 – for 200 mm distance and Figs. 21, 22, 23 and 24 – for 300 mm distance. The results of measurements are presented (Figs. 13, 17 and 21) according to two different procedures of averaging (left and right section of the Figures) of the velocity field. The processing of experimental data in each flow conditions was done by PIV measurements of approximately 20 to 25 instantaneous velocity fields and their time averaging. Two final types of velocity fields were obtained for each measuring conditions by subtracting either space averaged velocity vector or only the horizontal component of this vector from the time averaged velocity field. The origin of the coordinating system for each PIV intersection distance from hydrofoil was in taken in the center of the cavitating tip vortex. The homogeneous high velocity area in the vicinity of the origin should be analyzed with respect of remarks described in the conclusions section of this article.

Close inspection of the results for the plane located 50 mm behind the hydrofoil tip leads to several interesting observations:

- measurements indicate presence of two almost equally strong vortex kernels; such a situation may happen in specific flow cases, but in this case it is not confirmed by photographs and by calculations,
- predictions by CFX look almost the same for all turbulence models, what corresponds to the results of calculation of cavitation described above,
- predictions by Fluent depend strongly on the turbulence model,
- predictions by Fluent and CFX agree quite well with each other for k-ε RNG turbulence model,
- Fluent results show existence of the wake downstream of the hydrofoil, such effect is less visible in prediction by CFX, what arises from the mesh structure.

Analysis of Figs 17 – 20, describing the situation at 200 mm behind the hydrofoil, may be summarized in the following way:
- the measurements indicate the advancing process of concentration and merging of the two initially detected vortex kernels into one,
- calculation by Fluent and CFX indicate the process of turbulent dissipation of vorticity and resulting weakening of the vortex,
- this calculated process of dissipation of turbulent vorticity depends strongly on the model of turbulence; it seems to be overestimated in case of standard k-ε and k-ω SST models, what leads to prediction of too short cavitating tip vortex (cf. Figs. 9 – 12), because the calculated intensity of the vortex falls too rapidly with distance from the hydrofoil,
- the k-ε RNG turbulence model produces very similar results both in Fluent and CFX, moreover, they agree reasonably with the results of measurements as far as the maximum values of velocity are concerned.
- Fluent results still indicate existence of the wake downstream of the hydrofoil, its interaction with the vortex results in an asymmetric structure of the vortex, it is better shown for k-ε RNG and SST models (less dissipative than standard k-ε).

The situation at 300 mm behind the hydrofoil tip, shown in Figs. 21 – 24, may be summarized in the following way:
- measurements show a single strong vortex of a rather unnatural rectangular cross-section,
- as far as the calculations are concerned, only the results obtained from Fluent with k-ε RNG turbulence model produce maximum values of velocity comparable with that determined in the measurements,
- all other calculations predict too intensive dissipation of vorticity, what is confirmed by the cavitation prediction shown in Figs. 10 – 12
- the interaction of the tip vortex with the wake is still present in Fluent results.

CONCLUSIONS

The detailed analysis of the results of measurements, observations and CFD calculations presented in this article leads to the following conclusions:

- the contemporary commercial CFD codes are generally capable of predicting the geometry of the cavitating tip vortices generated by hydrofoils reasonably well,
- the accuracy of CFD prediction of the geometry of the cavitating tip vortex depends strongly on the turbulence models and on the grid structure, hence only the grids constructed especially for vortex-dominated flows should be used, together with turbulence models especially suited for modeling of such flows [1, 2, 3, 6],
- in view of the above presented results the turbulence model k-ε RNG seems to be best suited for CFD prediction of tip vortex cavitation, despite the fact that according to [3] the k-ω SST performed best in prediction of non-cavitating vortex flows,
- the measurements of the velocity field in the vicinity of the cavitating tip vortex by means of PIV methods seem to be a difficult and challenging task, especially due to the following reasons:
  o unsteady oscillations of the cavitating kernel of the vortex,
  o uncontrolled content of cavitation nuclei (i.e. gas and vapour filled micro-bubbles) carried by the flowing water,
  o shading of part of the measuring plane by the cavitating kernel,
  o difficulties in homogeneous PIV seeding due to the large volume of fluid inside the cavitation tunnel and complex flow conditions near cavitating tip vortex (centrifugal force acting on seeding particles)
- due to the above listed reasons the velocity distribution predicted numerically at the following sections is significantly different from the measurements.

INTRODUCTION

Grid stiffened cylindrical shells are applicable in many industries such as aerospace industries. Stiffened cylindrical shells play a big role in aerospace industries in fuselage and fuel tank applications. This has resulted in an extensive research work in the field of cylinders with stiffening structures [1–8].

Grid stiffened cylindrical shells are widely used in engineering fields. These structures are subjected to external dynamic loads. These external dynamic loads can cause the undesirable resonance and it can lead to fatigue. Moreover, dynamic characteristics must be used on design of structure because only vibration (not fatigue) could severely damage the sensitive equipment in airplanes, launch vehicles and etc. Therefore, it is essential to understand the dynamic behavior of these structures. Theoretical methods of analyzing the grid stiffened structures are classified into two main types, depending upon whether the stiffeners are treated by averaging their properties over the shell surface to conventional materials or by considering them as discrete elements. The first method, so-called smeared stiffener theory, is particularly applicable only when large numbers of stiffeners are closely and evenly spaced. The second method, so-called discrete stiffener theory, is more general as it can accommodate any stiffener distribution. Numerous researches have been developed to study the vibrational behavior of stiffened cylindrical shells. Mustafa and Ali [9] predicted natural frequencies for the stiffened cylindrical shells using the Rayleigh-Ritz procedure. In this procedure they used only one term in assuming the displacement functions satisfying the simply supported boundary condition. One-term approximation is sufficient for the analysis of the cylindrical shells with simply supported boundary condition. However, it can lead to much error to obtain the exact solution of stiffened shells with any other boundary conditions. Yang and Zhou [10] presented the transfer function method to analyze the ring-stiffened shell. Lee and Kim [11, 12] investigated the effect of rotation speeds and boundary conditions on the frequencies for the orthogonally stiffened composite cylindrical shells treating the materials of stiffeners as equivalent isotropic. The mentioned papers were, however, limited to the shells with the uniform dimensional and evenly spaced stiffeners. In fact, non-uniform dimensional and unevenly spaced stiffeners are used much more in structural reinforcements. Wang et al. [13] solved the free vibration problem for the isotropic cylindrical shells with varying ring-stiffener distribution using the extended Ritz method. Egle and Sewall [14], in different boundary conditions, have analyzed the effect of stiffeners on natural frequencies of stiffened cylindrical shells. In this research, stiffeners are considered as discrete elements, energy method and Hamilton principle are used to obtain equations of motion. Rinehart and Wang [15] have studied the changes in natural frequencies of cylindrical shells affected by stringers stiffeners, based on Vlasov thin walled beam theory. By both, considering the stiffeners as discrete elements and using energy method, they have obtained the equations of motion.

Unlike the previous study, the vibrations of stiffened cylindrical shells with grid structure under full free boundary conditions are analyzed in this paper. The stiffness matrix of the whole structure is determined by stiffness matrix of grid structures. Then, equilibrium equations are considered based...
on the classical shell theory. Strain-displacement relations are written based on the first approximation of Love theory and then by replacement in stress-strain relations, equilibrium equations based on displacement parameters are obtained. After simplification of equilibrium equations, the shell frequency equation is obtained by using Galerkin method. Finally, according to the following assumptions, the effect of stiffener geometry and mass of grid stiffened cylindrical shell on natural frequencies is presented:

1. The thickness of ribs is small compared with length of the ribs. So the transverse strain of stiffeners is much smaller than that of longitudinal strain and can be negligible.
2. The strain is uniform across the cross-sectional area of the stiffeners. Hence, a uniform stress distribution is assumed across the cross-sectional area of the stiffeners.
3. The load on the stiffener/shell is transferred through shear forces between the stiffeners and shell.

**ANALYTICAL METHOD**

**Equivalent Stiffness Matrix of the Stiffener and Shell**

To calculate the natural frequencies of the whole structures, first, the stiffness matrix of grid structures must be determined. This matrix is composed of three separated matrices $A^s$, $B^s$ and $D^s$ which can be explained like below:

$$
\begin{bmatrix}
N^s \\
M^s
\end{bmatrix} = \begin{bmatrix}
A^s & B^s \\
B^s & D^s
\end{bmatrix} \begin{bmatrix}
\varepsilon^0 \\
\gamma^0
\end{bmatrix}
$$

(1)

Based on geometrical variables of grid structures which presented in Fig. 1, stiffness matrix of grid structures can be obtained as below [16]:

$$
\begin{bmatrix}
N_x \\
N_0 \\
N_{0x} \\
M_x \\
M_0 \\
M_{0x}
\end{bmatrix} = AE
$$

(2)

$$
\begin{bmatrix}
2\frac{c^3+1}{a} & 2\frac{cs^2}{a} & 0 & \frac{c^3+1}{a} & \frac{cs^2}{a} & 0 \\
2\frac{cs}{b} & 2\frac{s^3+1}{b} & 0 & \frac{c^2st}{b} & \frac{s^3+1}{b} & 0 \\
0 & 0 & 2\frac{s^2c}{a} & 0 & 0 & \frac{s^2ct}{a} \\
\frac{c^3+1}{t} & \frac{cs^2t}{a} & 0 & \frac{c^3+1}{2a} & \frac{cs^2t^2}{2a} & 0 \\

\end{bmatrix}
$$

(3)

The above matrix elements are the functions of the strain and curvature parameters of the shell. We denote these stiffness parameters by $A^s$, $B^s$ and $D^s$ which corresponds to the extensional, coupling and bending matrices, respectively. Here, the superscript $s$ stands for stiffener. By the matrix summation of force and moment, coming from the stiffener Grid structure and cylindrical shell, the force and the moment of the whole structure will be obtained.

$$
\begin{bmatrix}
N \\
M
\end{bmatrix} = \begin{bmatrix}
N^s + N^{sh} \\
M^s + M^{sh}
\end{bmatrix}
$$

(4)

$N^s$ and $M^s$ are the force and moment contribution of the shell, respectively. Forces and moments, which affect the shell,
x axis is taken in the axial direction of the shell, where the θ and z axes are in the circumferential and radial directions of the shell, respectively. The displacements of the shell are defined by u, v, w in the x, θ, z directions respectively.

The equations of motion for a cylindrical shell can be written by the Love theory as:

\[
\begin{bmatrix}
L_{11} & L_{12} & L_{13} \\
L_{21} & L_{22} & L_{23} \\
L_{31} & L_{32} & L_{33}
\end{bmatrix}
\begin{bmatrix}
u \\
w
\end{bmatrix} = \begin{bmatrix}
0 \\
0
\end{bmatrix}
\]

where:

\[L_{ij}(i, j = 1, 2, 3)\] — the differential operators with respect to x and θ.

**Boundary Conditions**

Due to the satisfaction of the boundary conditions, the displacement u, v and w can be explained as double Fourier series [19]:

\[
u(x, θ, t) = \sum_{m=0}^{n} \sum_{n=0}^{\infty} A_{mn}(x) \frac{\partial \varphi_{mn}(x)}{\partial x} \cos(nθ) \cos(ωt)
\]

\[
u(x, θ, t) = \sum_{m=0}^{n} \sum_{n=0}^{\infty} B_{mn}(x) \phi_{mn}(x) \sin(nθ) \cos(ωt)
\]

\[
u(x, θ, t) = \sum_{m=0}^{n} \sum_{n=0}^{\infty} C_{mn}(x) \cos(nθ) \cos(ωt)
\]

In recent equations, A_{mn}, B_{mn} and C_{mn} are coefficients of natural modes’ shape, which obtained from solving free vibration. For solving free vibrations, T_{mn}(t) = e^{ωt} is considered as a function of time, m is the number of axial half-wavelength, n is the number of circumferential half-wavelength and ω_{mn} is the natural frequency in mode of mn. To satisfy boundary conditions, axial and circumferential functions are explained as below:

\[
\varphi_{mn}(x) = A_{mn} \cosh\left(\frac{\lambda_{mn} x}{L}\right) + A_{mn} \sinh\left(\frac{\lambda_{mn} x}{L}\right) - A_{mn} \sigma_{mn} \cosh\left(\frac{\lambda_{mn} x}{L}\right) - A_{mn} \sigma_{mn} \sinh\left(\frac{\lambda_{mn} x}{L}\right) (i = u, v, w)
\]

In above equations, \(\sigma_{mn}\) are constant coefficients which determined according to boundary conditions. \(\lambda_{mn}\) is the root of non-linear equations and \(\sigma_{mn}\) is the dependant parameter on \(\lambda_{mn}\), which obtained according to boundary conditions. Free-Free supported conditions can be defined as below:

\[
\frac{\partial^{2} \varphi}{\partial x^{2}} = 0, \quad \frac{\partial^{3} \varphi}{\partial x^{3}} = 0
\]  

**Free Vibration Analysis**

Using Galerkin method and substituting Eq. 7 into Eq. 6, it can be written as:

\[
\begin{bmatrix}
c_{11} & c_{12} & c_{13} \\
c_{21} & c_{22} & c_{23} \\
c_{31} & c_{32} & c_{33}
\end{bmatrix}
\begin{bmatrix}
A_{mn} \\
B_{mn} \\
C_{mn}
\end{bmatrix} = 0
\]

where:

\[C_{ij}(i, j = 1, 2, 3)\] — the parameters from the L_{ij} after they are operated with the x and θ.

For non-trivial solutions, one sets the determinant of the characteristic matrix in Eq. 9 to zero:

\[
det(C_{ij}) = 0 (i, j = 1, 2, 3)
\]

So the frequency equation can be obtained as:

\[
\beta_{1} ω^{6} + \beta_{2} ω^{4} + \beta_{3} ω^{2} + \beta_{4} = 0
\]

where:

\[\beta_{i}(i, j = 1, 2, 3)\] — the coefficients of Eq. 10.

Solving Eq. 11, one obtains three positive roots and three negative roots. The three positive roots are the angular natural frequencies of the cylindrical shell in the axial, circumferential and radial directions. The lowest of the three positive roots represents the flexural vibration, and the other two are in-plane vibrations.

**NUMERICAL RESULTS AND DISCUSSION**

Numerical implementation of the present analysis was performed using general-purpose computation package MATLAB. To check the accuracy of the present analysis, the results obtained are compared with those in the [17]. A comparison of the values of the frequency of a free vibrating cylindrical shell with the F-F boundary conditions is given in Table 1.

In the parameter, E is Young’s modulus of elasticity, \(v\) is the Poisson ratio, \(ρ\) is the density, R is the radius and \(ω\) is the frequency. The comparisons are carried out for the parameter of L/R = 2.63 and for the cases of R/h = 374 and t = 6.477x10^{4} m.

Using the method outlined earlier, numerical results are obtained for the six model of grid-stiffened cylinder with four families of ribs and geometric and mechanical parameters given in Tables 2 and 3.

The obtained results are compared to the solution of the same problem when the considered structures are modeled with a finite element analysis package ANSYS. One of the generated mesh by this package is shown in Fig. 3.

Fig. 3. The mesh generated for a grid stiffened cylindrical shell using ANSYS

Based on a technical report [18], natural frequencies of a grid-stiffened shell can be approximated by equivalent of thickness. In this method, a conventional shell with the same weight as grid part is predicted. An equivalent shell will be produced by the replacement of this shell with grid part. The obtained frequencies of this equivalent shell can be a proper approximation for natural frequencies of the main structure. In Figs. 4-9, a comparison between the results obtained by ETM (Equivalent Thickness Method), FEM and present method is presented. These figures have shown that the present method gives more exact answers than ETM.

Fig. 10 shows the changes relative to natural frequencies of six predicted models, according to the angle of helical ribs. As shown in this figure, when the angle of helical rib increases, the amount of natural frequencies of structures will be increased.
with the present method and the agreement between them was good. Based on comparisons of the mentioned method, it is concluded that the present method is more convenient, more effective and more accurate.

Theoretical and mathematical models of the torque of mechanical losses in the pump used in a hydrostatic drive

Zygmunt Paszota, Prof.
Gdansk University of Technology

INTRODUCTION

The paper is a continuation of the work presented in references [1 ÷ 18], aimed at creating a method of evaluation of the losses and energy efficiency of hydrostatic drives as well as the used displacement machines (pump and hydraulic motors). The method is based on mathematical models of energy losses in the pumps, in hydraulic motors and in other elements of a hydrostatic drive system.

The description of pump losses and energy efficiency is based on the diagram of power increase in the drive system opposite to the direction of power flow, replacing the Sankey diagram of power decrease in the direction of power flow [18]. The Sankey diagram of decrease (division) of power in a drive system in the direction of power flow is the main reason of incorrect evaluation of the energy losses, a. o. in the displacement pumps and hydraulic motors used in hydrostatic drive systems.

During the operation of a hydrostatic drive system, the energy losses force the increase of power in the system – from useful power \( P_{Mu} \) required by the hydraulic motor driven machine to the power \( P_{PC} \) consumed by the pump on the pump shaft.

In the description of power flow in a drive system and the powers of energy losses connected with the flow, the notions: „power decrease”, „power division”, „power loss” should not be used.

The notion associated with the power of energy losses in a drive system is „increase of power”.

Figure 1 presents a diagram of power increase in a displacement pump opposite to the direction of power flow, which replaces the Sankey diagram of power decrease in the direction of power flow.

ABSTRACT

The paper presents theoretical and mathematical models of the torque of mechanical losses in the pump with theoretical (constant) capacity \( q_{Pt} \) per one shaft revolution (with constant theoretical working volume \( V_{Pt} \)) and geometrical (variable) capacity \( q_{Pgv} \) per one shaft revolution (with variable volume \( V_{Pgv} \)). The models may be used in the laboratory and simulation investigations of the pump energy efficiency and the hydrostatic drive efficiency.

Key words: hydrostatic drive; displacement pump; energy efficiency

THEORETICAL MODELS OF THE TORQUE \( M_{pM} \) OF MECHANICAL LOSSES IN THE PUMP „WORKING CHAMBERS - SHAFT” ASSEMBLY

The pump shaft torque \( M_{p} \) (required by the pump of its driving motor) must be greater than the torque \( M_{pi} \) indicated in the pump working chambers because of the necessity of balancing also the torque \( M_{pm} \) of mechanical losses in the „working chambers – shaft” assembly. The assembly forms the working chambers and changes their capacity and also connects the working chambers with the shaft. Therefore, the torque \( M_{pi} \) required on the pump shaft is a sum of the torque \( M_{pi} \) indicated in the working chambers and the torque \( M_{pm} \) of mechanical losses in the pump „working chambers – shaft” assembly:

\[
M_{p} = M_{pi} + M_{pm} \tag{1}
\]

Torque \( M_{pm} \) of mechanical losses in a pump with variable capacity \( q_{Pgv} \) per one shaft revolution is, at the maximum value of \( q_{Pgv} \), i.e. \( q_{Pgv} = q_{Pt} \) (with \( b_{p} = q_{Pgv}/q_{Pt} = 1 \), equal to the torque...
of mechanical losses in that pump working as a pump with constant capacity $q_T$ per one shaft revolution. The theoretical and mathematical models describing the torque $M_{m}$ of mechanical losses in a pump with variable capacity $q_{P}$ per one shaft revolution may be based on models of $M_{m}$ describing the torque of mechanical losses in a pump with constant capacity $q_T$ per one shaft revolution (with $b = 1$). Considering the models describing the torque of pump mechanical losses, we assume, that the pump is driven with practically constant rotation speed $n_P$, and the decrease of shaft speed (decrease of the pump driving motor speed as a result of the increase of torque $M_{p}$ loading the motor shaft) to a value $n_P < n_{p0}$ ($n_{p0}$ – rotational speed of unload pump driving motor) is negligible from the point of view of the impact of speed $n_P$ on the value of torque $M_{m}$ of mechanical losses.

Torque $M_{m}$ of mechanical losses in the pump is mainly an effect of friction forces between elements of the "working chambers – shaft" assembly, depending, among other, on the torque $M_{i}$ indicated in the working chambers – $M_{i} = q_{P} \Delta p_{Pi} / 2 \Pi = b_{P} q_{T} \Delta p_{Pi} / 2 \Pi$.

Friction forces between elements of the "working chambers – shaft" assembly are, to some extent, also an effect of the load on those elements of the inertia forces from rotational and reciprocating motion and depend on the pump capacity $q_{P}$ per one shaft revolution ($b_{P}$ coefficient).

In the piston (axial or radial) pumps with casing (crankcase) filled with liquid, friction forces also occur between elements of the "working chambers – shaft" assembly and the liquid and depend on the liquid viscosity $\nu$.

The value of torque $M_{m} = q_{P} \Delta p_{Pi} / 2 \Pi$ of mechanical losses in the pump "working chambers – shaft" assembly and the liquid and depend on the liquid viscosity $v$.

The impact of inertia forces of the "working chambers – shaft" assembly elements, performing the rotational and reciprocating motion in the pump, on the torque $M_{m}$ of mechanical losses can be presented, under the assumption that rotational speed $n_{P}$ of the pump driving motor changes only in a small range, as a function of capacity $q_{P}$.

In the theoretical and mathematical models describing the torque $M_{m}(\Delta p_{Pi}, b_{P}, \nu_{n})$ of mechanical losses in the pump is proportional to the increase $\Delta p_{Pi}$ of pressure in the pump working chambers.

In the theoretical and mathematical models describing the torque $M_{m}(\Delta p_{Pi}, b_{P}, \nu_{n})$ of mechanical losses in the pump is proportional to the increase $\Delta p_{Pi}$ of pressure in the pump working chambers.
Fig. 2. Torque $M_{pm|\Delta p_{pi}=1,b_p=1,\nu}$ of mechanical losses in the pump with constant capacity $q_{Pt}$ per one shaft revolution ($b_p = 1$), with working liquid reference viscosity $\nu_n$, as a function of the indicated increase $\Delta p_{Pi}$ of pressure in the pump working chambers – graphical interpretation of theoretical model (2).

Fig. 3. Torque $M_{pm|\Delta p_{pi}=0,b_p=1,\nu}$ of mechanical losses in a piston (axial or radial) pump with crankcase filled with liquid and with constant capacity $q_{Pt}$ per one shaft revolution ($b_p = 1$), at the indicated increase $\Delta p_{Pi} = 0$ of pressure in the pump working chambers, as a function of the ratio of viscosity $\nu$ to reference viscosity $\nu_n$, $\nu/\nu_n$ – graphical interpretation of theoretical model (3); torque $M_{pm|\Delta p_{pi}=0,b_p=1,\nu}$ of mechanical losses in the pump without the crankcase filled with liquid is practically independent of the liquid viscosity $\nu$ and is determined at the liquid reference viscosity $\nu_n$ ($b_p$ coefficient) per one shaft revolution of a variable capacity pump.

Inertia forces do not depend on the value of increase $\Delta p_{Pi}$ of pressure in the working chambers, therefore their impact on the torque $M_{pm}$ of mechanical losses in the pump may be included in the evaluation of the torque $M_{pm|\Delta p_{pi}=0,b_p,\nu_n}$ of mechanical losses determined at the increase $\Delta p_{Pi} = 0$ (Fig. 5).

The impact of the friction forces between the “working chambers – shaft” assembly elements and the liquid in the casing (crankcase) of the piston pump on the torque $M_{pm}$ of mechanical losses in the pump can be presented, under the assumption that speed $n_p$ changes in a small range, as a relation of $M_{pm}$ to the viscosity $\nu$ and to the capacity $q_{Pgv}$ ($b_p$ coefficient) per one shaft revolution (Fig. 3, 4, 6, 7).

It is assumed, that the impact of liquid viscosity $\nu$ on the friction forces between the “working chambers – shaft” elements and the liquid in the piston pump casing (crankcase), and in effect on the torque $M_{pm}$ of mechanical losses in the pump, can be evaluated at one level of the increase $\Delta p_{Pi}$ of pressure indicated in the working chambers, e.g. at the increase $\Delta p_{Pi} = 0$ (Fig. 3, 6). This assumption is connected with a simplification assuming that there is no significant impact of the increase $\Delta p_{Pi}$ of pressure on the liquid viscosity $\nu$ and with assuming in the model describing the torque $M_{pm}$ of mechanical losses the liquid viscosity $\nu$ determined in the pump inlet conduit [at pressure $p_{P1}$ equal to zero (at liquid absolute pressure equal to atmospheric pressure)].
The impact of inertia forces of structure elements performing the rotational or reciprocating motion in the pump and also the impact of liquid viscosity $\nu$ on the torque $M_{pm}$ of mechanical losses in the pump is then described in the model of the torque $M_{pm|\Delta p_{pi}=0,b_p,\nu}$ of those losses in an unloaded pump (at $\Delta p_{pi} = 0$) supplied with working liquid of changing viscosity $\nu$.

The proposed theoretical models describing the torque $M_{pm|\Delta p_{pi}=0,b_p,\nu}$ of mechanical losses in an unloaded pump (at the indicated increase $\Delta p_{pi} = 0$ of pressure in the working chambers) and at changing working liquid viscosity $\nu$ [the impact of liquid viscosity $\nu$ occurs in the piston pumps with liquid filling the casing (crankcase)] have the form:

- in the pump with theoretical (constant) capacity $q_{pt}$ ($b_p = 1$) per one shaft revolution (Fig. 3):

$$M_{pm|\Delta p_{pi}=0,b_p=1,\nu} = M_{pm|\Delta p_{pi}=0,b_p=1,\nu} \left( \frac{\nu}{\nu_n} \right)^{a_{\nu m}}$$ (3)

- in the pump with geometrical (variable) capacity $q_{pgv}$ ($q_{pgv} = b_p q_{pt}$) per one shaft revolution (Fig. 6):

$$M_{pm|\Delta p_{pi}=0,b_p,\nu} = (M_{pm|\Delta p_{pi}=0,b_p=0,\nu} + \Delta M_{pm|\Delta p_{pi}=0,b_p,\nu}) \left( \frac{\nu}{\nu_n} \right)^{a_{\nu m}}$$ (4)

where:

$$\Delta M_{pm|\Delta p_{pi}=0,b_p,\nu} = M_{pm|\Delta p_{pi}=0,b_p=0,\nu} - M_{pm|\Delta p_{pi}=0,b_p=0,\nu} =$$

$$= (M_{pm|\Delta p_{pi}=0,b_p=0,\nu} - M_{pm|\Delta p_{pi}=0,b_p=0,\nu}) b_p$$ (5)

Exponent $a_{\nu m}$ in expressions (3) and (4) describes the impact of the ratio $\nu/\nu_n$ of working liquid $\nu$ to reference viscosity $\nu_n = 35 \text{mm}^2\text{s}^{-1}$ on the value of torque of mechanical losses in a piston displacement machine with liquid filling the casing (crankcase) (in the pump and in the hydraulic motor).

The increase $M_{pm|\Delta p_{pi}=0,b_p,\nu}$ of the torque of mechanical losses in the pump, due to the load of the assembly elements with the indicated torque $M_p$, resulting from the indicated increase $\Delta p_{pi}$ of pressure in the pump working chambers, is independent of the inertia forces of elements performing the rotational or reciprocating motion in the pump. It is also practically independent of the working liquid viscosity $\nu$; therefore, it may be determined at one viscosity value, e.g. at the liquid reference viscosity $\nu_n$ (Fig. 4, 7).

The proposed theoretical models describing the increase $M_{pm|\Delta p_{pi}=0,b_p,\nu}$ of the torque of mechanical losses in the pump, resulting from the indicated increase $\Delta p_{pi}$ of pressure in the working chambers, have the form:

- in the pump with theoretical (constant) capacity $q_{pt}$ ($b_p = 1$) per one shaft revolution (Fig. 4):

$$\Delta M_{pm|\Delta p_{pi}=0,b_p=1,\nu} = \Delta M_{pm|\Delta p_{pi}=0,b_p=1,\nu} =$$

$$= (M_{pm|\Delta p_{pi}=0,b_p=1,\nu} - M_{pm|\Delta p_{pi}=0,b_p=0,\nu}) \frac{\Delta p_{pi}}{\nu_n}$$ (6)

- in the pump with geometrical (variable) capacity $q_{pgv}$ ($q_{pgv} = b_p q_{pt}$) per one shaft revolution (Fig. 7):

$$\Delta M_{pm|\Delta p_{pi}=0,b_p,\nu} = M_{pm|\Delta p_{pi}=0,b_p,\nu} - M_{pm|\Delta p_{pi}=0,b_p,\nu} =$$

$$= (M_{pm|\Delta p_{pi}=0,b_p=0,\nu} - M_{pm|\Delta p_{pi}=0,b_p=0,\nu}) b_p$$ (7)

...
In effect, the proposed theoretical models describing the torque $M_{pm}$ of mechanical losses in the pump take the forms:

1. In the pump with theoretical (constant) capacity $q_{pt} (b_p = 1)$ per one shaft revolution (Fig. 4):

$$M_{pm}|\Delta p_{pi}, b_p = 1, v_n = M_{pm}|\Delta p_{pi} = 0, b_p = 1, v_n \left( \frac{v}{v_n} \right)^{\alpha_{vm}} + \Delta M_{pm}|\Delta p_{pi}, b_p = 1, v_n, v_n \left( \frac{v}{v_n} \right)^{\alpha_{vm}} + (M_{pm}|\Delta p_{pi} = p_n, b_p = 1, v_n - M_{pm}|\Delta p_{pi} = 0, b_p = 1, v_n) \frac{\Delta p_{pi}}{p_n}$$

(8)

2. In the pump with geometrical (variable) capacity $q_{pgv} = b_p q_{pt}$ per one shaft revolution (Fig. 7):

$$M_{pm}|\Delta p_{pi} = 0, b_p = 0, v_n + \Delta M_{pm}|\Delta p_{pi} = 0, b_p = 1, v_n = \Delta M_{pm}|\Delta p_{pi}, b_p, v_n$$

(9)

$$\Delta M_{pm}|\Delta p_{pi} = 0, b_p, v_n = (M_{pm}|\Delta p_{pi} = 0, b_p = 1, v_n - M_{pm}|\Delta p_{pi} = 0, b_p = 0, v_n) b_p$$

(10)

$$\Delta M_{pm}|\Delta p_{pi}, b_p, v_n = (M_{pm}|\Delta p_{pi} = p_n, b_p = 1, v_n - M_{pm}|\Delta p_{pi} = 0, b_p = 1, v_n) b_p \frac{\Delta p_{pi}}{p_n}$$

(11)

MATHEMATICAL MODELS OF THE TORQUE OF MECHANICAL LOSSES

In the mathematical models describing the torque $M_{pm}$ of mechanical losses in the pump, components $k_i$ of losses are used relating (comparing) the components describing the torque $M_{pm}$ of losses in theoretical models to the pump theoretical torque $M_{pt}$. The pump theoretical torque $M_{pt}$ is also a reference value used in the description of the torque $M_{pt}$ indicated in the pump working chambers:

- theoretical torque:

$$M_{pt} = \frac{q_{pt} p_n}{2\Pi}$$

of the pump, with theoretical (constant) capacity $q_{pt}$ per one shaft revolution ($b_p = 1$), is determined with the increase $\Delta p_{pt}$ of pressure in the pump equal to the system nominal pressure $p_n - \Delta p_{pt} = p_n$ and with the assumption that there are no pressure and mechanical losses in the pump,

- indicated torque:

$$M_{pi} = \frac{p_{pt} \Delta p_{pi}}{2\Pi} = \frac{M_{pt} \Delta p_{pi}}{p_n}$$

in working chambers of the pump with theoretical (constant) capacity $q_{pt}$ per one shaft revolution ($b_p = 1$) is determined with the indicated increase $\Delta p_{pi}$ of pressure in the working chambers,

- indicated torque:

$$M_{pi} = \frac{q_{pgv} \Delta p_{pi}}{2\Pi} = \frac{b_p q_{pt} \Delta p_{pi}}{p_n}$$

in working chambers of the pump with geometrical (variable) capacity $q_{pgv} = b_p q_{pt}$ per one shaft revolution is determined with the indicated increase $\Delta p_{pi}$ of pressure in the working chambers.
The theoretical and mathematical models describe the torque $M_{pm}$ of mechanical losses in the pump with theoretical (constant) capacity $q_{p}$ per one shaft revolution or with geometrical (variable) capacity $q_{pgv}$ per one shaft revolution:

- $q_{p} = q_{p} / \Delta p_{pi} = b_{p} q_{pgv}$ is a theoretical capacity per one shaft revolution of the pump with constant capacity per one revolution ($b_{p} = 1$) determined at $\Delta p_{pi} = 0$, $p_{p1i} = 0$ and $v_{n}$, which is equal to the working volume of the working chambers created during one shaft revolution,

- $q_{pgv} = b_{p} q_{pgv}$ is a geometrical capacity per one shaft revolution of the pump with variable capacity per one revolution at $\Delta p_{pi} = 0$, $p_{p1i} = 0$ and $v_{n}$, which is equal to the working volume of the working chambers created during one shaft revolution.

The torque $M_{pm}$ of mechanical losses in a piston (axial or radial) pump with crankcase filled with liquid and with variable capacity $q_{pgv} = b_{p} q_{pgv}$ per one shaft revolution, at the indicated increase $\Delta p_{pi} = 0$ of pressure in the pump working chambers, as a function of the ratio of viscosity $\nu$ to reference viscosity $\nu_{n}$ – $\nu / \nu_{n}$ – graphical interpretation of theoretical model (4); capacity $q_{pgv}$ per one shaft revolution (coefficient $b_{p}$ of pump capacity): $q_{pgv} = 0$ ($b_{p} = 0$), $q_{pgv}$ ($b_{p}$), $q_{pgv} = q_{pgv}$ ($b_{p} = 1$). Torque $M_{pm}$ of mechanical losses in the pump without crankcase filled with liquid is practically independent of the liquid viscosity $\nu$ and is determined at the liquid reference viscosity $\nu_{n}$.
revolution. Capacity \( q_{Pgv} \) per one shaft revolution changes in the \( 0 \leq q_{Pgv} \leq q_{Pt} \) range and coefficient \( b_P = q_{Pgv}/q_{Pt} \) of the pump capacity changes in the \( 0 \leq b_P \leq 1 \) range.

The proposed mathematical models describing the torque \( M_{pm} \) of mechanical losses in the pump, related to theoretical models of the torque of mechanical losses, take the form:

- in a pump with theoretical (constant) capacity \( q_{Pt} \) per one shaft revolution \( (b_P = 1) \) [referring to theoretical model (8)]:

\[
M_{Pm}[\Delta P_Pi, v] = k_{4.1.1} M_{Pt}(\frac{v}{v_n})^{a_{vm}} + k_{4.2} M_{Pt} \frac{\Delta P_{Pi}}{p_n} = \]
\[
= [k_{4.1.1}(\frac{v}{v_n})^{a_{vm}} + k_{4.2} \frac{\Delta P_{Pi}}{p_n}] M_{Pt} = \] (12)

where:
\[
k_{4.1.1} = \frac{M_{Pm}[\Delta P_Pi=0, b_P=1, v_n]}{M_{Pt}} = \frac{\frac{\Delta P_{Pi}}{p_n}}{2\Pi} \] (13)

\[
k_{4.2} = \frac{\Delta M_{Pm}[\Delta P_Pi, b_P=1, v_n]}{M_{Pt}} = \frac{\Delta M_{Pm}[\Delta P_Pi=0, b_P=1, v_n]}{2\Pi} = \]
\[
= \frac{M_{Pm}[\Delta P_Pi=0, b_P=1, v_n]}{2\Pi} = \frac{\Delta P_{Pi}}{p_n} \] (14)

- in a pump with geometrical (variable) capacity \( q_{Pgv} \) \( (q_{Pgv} = b_P q_{Pt}) \) per one shaft revolution [referring to theoretical models (9), (10) and (11)]:

\[
M_{Pm}[\Delta P_Pi, v] = k_{4.1.1} + k_{4.1.2} b_P M_{Pt}(\frac{v}{v_n})^{a_{vm}} + k_{4.2} M_{Pt} \frac{b_P \Delta P_{Pi}}{p_n} = \]
\[
= [(k_{4.1.1} + k_{4.1.2} b_P) (\frac{v}{v_n})^{a_{vm}} + k_{4.2} \frac{b_P \Delta P_{Pi}}{p_n}] M_{Pt} = \]
\[
= [(k_{4.1.1} + k_{4.1.2} b_P) (\frac{v}{v_n})^{a_{vm}} + k_{4.2} b_P \frac{\Delta P_{Pi}}{p_n}] \frac{q_{Pt}P_n}{2\Pi} \] where:
\[
k_{4.1.1} = \frac{M_{Pm}[\Delta P_Pi=0, b_P=0, v_n]}{M_{Pt}} = \frac{\frac{\Delta P_{Pi}}{p_n}}{2\Pi} \] (16)

\[
k_{4.1.2} = \frac{M_{Pm}[\Delta P_Pi=0, b_P=1, v_n]}{M_{Pt}} - \frac{M_{Pm}[\Delta P_Pi=0, b_P=0, v_n]}{M_{Pt}} \]
\[
= \frac{\frac{\Delta P_{Pi}}{p_n}}{2\Pi} \] (17)

Commentary:

- The sum \( (k_{4.1.1} + k_{4.1.2}) \) of coefficients used in mathematical model (15) describing the torque \( M_{pm} \) of mechanical losses in the pump with geometrical (variable) capacity \( q_{Pgv} \) \( (q_{Pgv} = b_P q_{Pt}) \) per one shaft revolution is equal to coefficient \( k_{4.1} \) used in the mathematical model (12) describing the torque \( M_{pm} \) of mechanical losses in that pump working as a pump with theoretical (constant) capacity \( q_{Pt} \) per one shaft revolution:

\[
k_{4.1.1} + k_{4.1.2} = k_{4.1}. \]

- Coefficient \( k_{4.1.2} \) used in mathematical model (15) describing the torque \( M_{pm} \) of mechanical losses in the pump with geometrical (variable) capacity \( q_{Pgv} \) \( (q_{Pgv} = b_P q_{Pt}) \) per one shaft revolution is equal to coefficient \( k_{4.2} \) used in the mathematical model (12) describing the torque \( M_{pm} \) of mechanical losses in that pump working as a pump with theoretical (constant) capacity \( q_{Pt} \) per one shaft revolution.

**CONCLUSIONS**

1. The theoretical and mathematical models have been developed of the torque \( M_{pm} \) of mechanical losses in the „working chambers – shaft” assembly of a displacement pump with constant \( q_{Pt} \) \( (V_{Pt}) \) and variable \( q_{Pgv} \) \( (q_{Pgv} = b_P q_{Pt}) \) per one shaft revolution, which describes the relation of the torque \( M_{pm} \) of mechanical losses in the assembly to the torque:

\[
M_{Pi} = \frac{\Delta P_{Pi}}{2\Pi} = \frac{b_P \Delta P_{Pi}}{2\Pi} \] indicated in the pump working chambers and also to the working liquid viscosity \( v \) at the pump inlet, changing in the \( \nu_{min} \leq v \leq \nu_{max} \) range. It is assumed that a small change of the pump driving motor rotational speed \( n_p \) (due to the changing pump shaft torque \( M_{ps} \) loading the motor) practically does not influence the torque \( M_{pm} \) of losses.

The indicated torque \( M_{ps} \) in the pump working chambers and the working liquid viscosity \( v \) are parameters independent of the torque \( M_{pm} \) of mechanical losses in the „working chambers – shaft” assembly.
The models describe also the relation of torque $M_{p_m}$ to the capacity $q_{p_m}$ per one shaft revolution (coefficient $b_P = q_{p_m}/q_{p_t}$ of the pump capacity) in a pump with variable capacity per onerevolution.

The assumed change of $q_{p_m}$ ($b_P$) is in the $0 \leq q_{p_m} \leq q_{p_t}$ ($0 \leq b_P \leq 1$) range.

2. The mathematical models of the torque $M_{p_m}$ of mechanical losses are based on defined coefficients $k_i$ of energy losses relating the torque of mechanical losses to a reference value, i.e. to:

- theoretical torque $M_{p_t}$ of a pump with theoretical (constant) capacity $q_{p_t}$ per one shaft revolution, determined at the increase $\Delta p_{p_t}$ of pressure in the pump equal to the nominal pressure $p_n$ of system operation ($\Delta p_{p_t} = p_n$), with:
  - known values of the pump capacity coefficient $b_P = q_{p_m}/q_{p_t}$, 
  - assumption of practically constant pump speed $n_p$ equal to the speed $n_{p_0}$ of the unloaded pump shaft ($n_p = n_{p_0}$).

3. The mathematical models of the torque $M_{p_m}$ of mechanical losses in the „working chambers – shaft” assembly should correspond with the models of volumetric losses in the working chambers and with the models of pressure losses in the pump channels.

The semi-Markov model of energy state changes of the main marine internal combustion engine and method for evaluating its operation during ship voyage

Jerzy Girtler, Prof.
Gdansk University of Technology

ABSTRACT

The article presents a method for evaluating the operation of internal combustion engines used as the main engines in the propulsion systems of sea-going ships in various operating conditions. This method enables calculating the engine operation value based on the theory of semi-Markov processes and mathematical statistics. What is noteworthy, the operation of the examined internal combustion engines is compared to a physical quantity which is expressed in the form of a number with the measure unit called joule-second. A model having the form of a semi-Markov process is proposed to describe the energy state changes taking place in the main engines during their operation. Also proposed is the use of the point and interval estimation at a given confidence level \( \beta \) for determining the value of the energy converted in the engine during its operation for the known and unknown standard energy deviation treated as the random variable. The semi-Markov model of changes of the energy converted in the engine during its operation is presented in a general form. The above model was used for determining the ship's main engine operation, which is in the examined case a function of the energy converted in particular energy states, the expected value of the time of duration of these states and the probability of their existence. These probabilities compose the limiting distribution of the semi-Markov process, the values of which are the specified main engine energy states.

Key words: operation; energy; semi-Markov process; piston internal combustion engine

INTRODUCTION

References [2, 4, 6, 12, 13] present a proposal to investigate the operation of internal combustion engines as the effect of the existence of their energy states which makes it possible to convert the delivered energy \( E \) and transmit it in time \( t \) to the energy receivers, such as propeller screws, pumps, compressors, etc. For the operation understood in the above way a method was proposed to valuate the operation of diesel engines used in shipbuilding in a general formulation taking into account the engine wear [2, 6]. Ref. [2] discusses the operation of the abovementioned internal combustion engines used as the main engines in the propulsion systems of sea-going ships taking into account the fact that correct operation of these engines requires securing delivery of sufficient amount of energy to its receivers, which are the propeller screws. The method presented in that article makes use of the deterministic model of engine operation which takes into account ship sailing conditions.

This article presents a stochastic model in the form of a semi-Markov process to model the changes of energy states of an arbitrary main engine, and the method for valuating the operation of those engines using this model. Like in Ref. [2], it was assumed here that the operation \( D \) can be compared to the physical quantity being the product of energy \( E \) and time \( t \) of its conversion, i.e. \( D = E \cdot t \).

The above interpretation of the operation of piston internal combustion engines results from the application of the analogy method (the intermediate method between induction and deduction), which makes it possible to transmit the observations from one object of investigation (empirical system) to another. Like in Ref. [2], the inspirations for developing the here presented method were proposals by P. L. Maupertius and W. R. Hamilton to consider the operation of a mechanical system as a physical quantity which reflects changes of mechanical energy in time. In classical physics an interpretation of the operation can be found which considers it the effect of the change of energy in time, expressed in the form of the product of energy and time, with the joule-second (joule×second) as the resultant measure unit.

In this formulation distinction is made between the operation [18, 19]:

- of the mechanical system (system of material points) being the result of kinetic and potential energy changes, which is referred to as the Hamilton operation \( (D_h) \) and
- resulting from the change of only the kinetic energy of the mechanical system (body), called the Maupertius operation \( (D_m) \).

A similar interpretation of the operation was adopted in quantum mechanics with respect to the source of...
The quantity \( D = L \cdot t \) or \( D = N \cdot t^2 \), as it may happen that the work and the time of its realisation, represented by information can only be obtained from a combined analysis of their power or work does not give comprehensive evaluation of engine capability to perform the task. This evaluation of engine operation is insufficient for full assessment of its energy conversion related qualities. Obviously, the engine power is an important parameter, as it contains the information how quickly the work can be done. But the operation in the above presented formulation is also important as it contains the information how long the engine can work. Since obtaining the required work \( (L) \) via conversion of the energy \( (E) \) is accompanied by energy losses in the form of heat \( (Q) \), therefore it is more reasonable to analyse energy changes, and not only engine work during engine operation.

The advantage of the interpretation of diesel engine operation proposed by the author is that the earlier descriptive evaluation of engine operation, for instance: the operation is good, bad, etc., can be replaced by the assessment based on comparing the engine operation with the reference standard operation using numbers and the measure unit, which is the joule-second.

The sense of the above interpretation of the operation of an engine, and in general any power generation device, can also be justified by the observation that changes of motion of a body depend on the force \( (F) \) acting on this body and the time \( (t) \) during which this action takes place. Body’s capability to move is expressed by the product of force and time \( (F \cdot t) \) bearing the name of the impulse of force \([9]\). The measure unit of the impulse of force is the newton-second. By analogy, we can conclude that the operation \( (D) \) of the diesel engine depends on work \( (L) \) done by this engine and time \( (t) \) of its operation, i.e. \( D = L \cdot t \).

Achievements in classical physics and quantum mechanics in this area were the motivations for the author to introduce the operation understood in the above way also to the technique, giving it a specific interpretation for particular power generation devices, including diesel engines. During the operation of these engines the energy conversion also takes place. The energy is first converted into heat \( (Q) \) and then into work \( (L) \). In the former case the chemical energy collected in the fuel-air mixture is converted into the internal energy of the exhaust gas, which bears the name of the thermal energy. This process takes place during fuel combustion. In the latter case, in turn, the internal energy in the exhaust gas is converted into the mechanical (kinetic and potential) energy of the moving piston. Obviously, the above energy conversion processes are accompanied with losses.

Such an approach to engine operation seems to be more favourable, as comparing energy conversion related advantages of particular engines based solely on the analysis and evaluation of their power or work does not give comprehensive information of the engine capability to perform the task. This information can only be obtained from a combined analysis of the work and the time of its realisation, represented by the quantity \( D = L \cdot t \) or \( D = N \cdot t^2 \), as it may happen that the engine is capable to convert the required energy to get the work \( L \), but the time \( t \) which it needs for doing this is longer than the required time \( (\text{for instance, excessively long time of duration of transient processes, so-called unsteady states, in the engine before it is fully loaded}) \). Or, it may happen that the work \( L = N \cdot t \) needed for performing the assumed task will not be done by the engine in a given time \( t \) (for instance, due to excessively small power output \( N \) of the engine resulting from its wear). Hence the conclusion that evaluating the correctness of engine operation based only on its power or work, without simultaneously taking into account the time of engine operation, is insufficient for full assessment of its energy conversion related qualities. Obviously, the engine power is an important parameter, as it contains the information how quickly the work can be done. But the operation in the above presented formulation is also important as it contains the information how long the engine can work. Since obtaining the required work \( (L) \) via conversion of the energy \( (E) \) is accompanied by energy losses in the form of heat \( (Q) \), therefore it is more reasonable to analyse energy changes, and not only engine work during engine operation.

The advantage of the interpretation of diesel engine operation proposed by the author is that the earlier descriptive evaluation of engine operation, for instance: the operation is good, bad, etc., can be replaced by the assessment based on comparing the engine operation with the reference standard operation using numbers and the measure unit, which is the joule-second.

The conditions of main engine operation are defined \([11, 16, 17] \):

- **External characteristic of maximal power** \( N_{\text{emax}} (h_{\text{max}} = \text{idem}) \),
- **External characteristic of continuous operating power** \( N_{\text{et}} \),
- **External characteristic of partial power** \( N_{\text{ep}} \),
- **External characteristic of nominal power** \( N_{\text{n}} \),
- **External characteristic of maximal power** \( N_{\text{max}} (b_{\text{max}} = \text{idem}) \).

A sample realisation of power changes of the main engine during its operation is shown in Fig. 1 \([2]\). The effective power \( N_e \) generated by the main engine characterises the engine operation in the aspect of rate of energy conversion into work, taking into account various types of losses, in particular thermal loss. However, engine operation consisting in energy conversion into work is not possible if this energy is not earlier converted into heat in the engine working spaces \([2, 15]\). Therefore when analysing the main engine operation we should take into account the energy delivered to the engine in the fuel-air mixture, which is first converted into heat \( (Q) \) and then into work \( (L) \), rather then the pure engine power output.
The analysis can be performed using a deterministic or stochastic model for describing real main engine energy change processes. The deterministic model of energy state changes taking place in the main engine during its operation was presented and discussed in Ref. [2]. This article presents the stochastic model of these changes having the form of a semi-Markov process.

MODEL OF ENGINE OPERATION IN THE FORM OF A SEMI-MARKOV PROCESS

Developing the model of internal combustion engine operation in the form of the semi-Markov process requires the application of the theory of semi-Markov processes. The publications on the semi-Markov processes give definitions of this process which differ by the range of generality and precision [3, 7]. For the purpose of modelling changes of the internal combustion engine energy states the semi-Markov process (family of random variables) \( \{X(t): t \geq 0\} \) at \( T = [0, +\infty) \), can be defined using a so-called homogeneous markovian process of recovery [7].

The semi-Markov model of an arbitrary real process can be only constructed when the states of this process can be defined in such a way that the time of duration of the state existing in time \( \tau_k \) and the state which is to be obtained in time \( \tau_{k+1} \) do not depend stochastically on the states which earlier took place, nor the time intervals of those states.

Constructing the semi-Markov model \( \{X(t): t \geq 0\} \) of the real process of energy state changes taking place in the diesel engine operation phase is possible, because [3]:

1) the Markov condition is fulfilled which says that the future evolution of an arbitrary process of the energy state changes taking place during engine operation depends solely on the engine state at a given time instant and not on the past engine operation, consequently the future state of this process and the time of its duration depend on the present and not on the past,

2) random variables \( T_k \), which represent the time of duration of the state \( e_i \) irrespective of the fact which state will be the next, and \( T_{k+1} \), which represent the time of duration of the state \( e_j \) on condition that the next state of this process is the state \( e_i \), have distributions different than the exponential distribution.

When analysing changes of the main engine energy states \( e_i \) resulting from converting particular energies \( E_i (i = 1, \ldots, 4) \) in the interpretation expressed by formula (1) for engine operation which enables the ship to perform the transporting task in a relatively long time, theoretically tending to infinity \( t \to \infty \), we can omit time intervals connected with changes of energy states \( e_i \) taking place when the energy converted in the engine working spaces increases from \( E_i \) to \( E_{i+1} \) to generate engine power output corresponding to those energies (1) in given time intervals (Fig. 1). Consecutive power outputs \( N_j (j = 1, \ldots, 4) \) can be considered the effects of the engine energy states \( e_i \in E_e (j = 1, \ldots, 4) \) of the stochastic process \( \{X(t): t \geq 0\} \), each of which takes a constant values in the time interval \([\tau_{in}, \tau_{in+1})\).

That means that the semi-Markov process \( \{X(t): t \geq 0\} \) is the process having the realisations constant in intervals and continuous on the right. Therefore the process is discrete in states and continuous in time, a sample fragment of the realisation \( x(t) \) of this process is shown in Fig. 2. This realisation reflects the situation when, following the elapsed time \( t \), successive state changes of this process take place in successive time intervals \([\tau_{in}, \tau_{in+1})\).

In case of marine main engines, in an arbitrary time of their operation the process \( \{X(t): t \geq 0\} \) can take one of the energy states existing during engine operation and belonging to the set:

\[
E_e = \{e_1, e_2, e_3, e_4\} \quad (2)
\]

with elements having the following interpretation (Fig. 1):

- \( e_1 \) — engine energy state resulting from generation of energy \( E_1 \) corresponding to engine load with partial power \( N_1 = N_{ec} \).
- \( e_2 \) — engine energy state resulting from generation of energy \( E_2 \) corresponding to engine load with (continuous) operating power \( N_2 = N_{en} \).
- \( e_3 \) — engine energy state resulting from generation of energy \( E_3 \) corresponding to engine load with nominal power \( N_3 = N_{nm} \).
- \( e_4 \) — engine energy state resulting from generation of energy \( E_4 \) corresponding to engine load with maximal power \( N_4 = N_{max} \).

Making distinction between those energy states differing by engine load is important because these states originate from the principles of diesel engine operation and are connected with the need for precise positioning of the fuel lever corresponding to particular loads [11, 15, 16, 17].

According to the presented model of energy state changes in the form of the process \( \{X(t): t \geq 0\} \), an arbitrary main engine which is in state \( e_i \) during its operation can reach, due to load increase, the state \( e_{i+1} \) with the probability \( p_{ij} \) after time \( T_{ij} \), and then reach the state \( e_{i+2} \) with the probability \( p_{ij} \) after time \( T_{ij} \). The state \( e_i \) of the process \( \{X(t): t \geq 0\} \) will take place when an arbitrary main engine starts converting energy \( E_i \). In a similar way, from the state \( e_i \) the process can reach the state \( e_{i+1} \) with the probability \( p_{i1} \) after time \( T_{i1} \), or the state \( e_{i+2} \), which can take place with probability \( p_{ii} \) after time \( T_{ii} \), etc.

A characteristic feature of the presented model of main engine energy state changes \( \{X(t): t \geq 0\} \) is that the change of the state \( e_i \) into the state \( e_{i+1} \) only depends on the properties of the state \( e_i \) and not on the previous states. This feature justifies the opinion that it is the semi-Markov process.

In this process the set of states \( E_e = \{e_1, e_2, e_3, e_4\} \) is finite. The elements composing this set are the values of the semi-Markov process \( X(t): t \geq 0 \). Changes of states in this process take place at times \( \tau_i = 0, \tau_i, \tau_{i+1}, \ldots \) and after the lapse of time intervals of their duration (Fig. 2) being random variables with different distributions. The state changes in this process take place with the following probability:

\[
P(X(\tau_{n+1}) = e_j | X(\tau_n) = e_i, X(\tau_{n-1}), \ldots, X(\tau_0), \tau_n = \tau_{n-1}, \ldots, \tau_1, \tau_0) = \quad (3)
\]

where:

- \( e_i, e_j \in E_e, i, j = 1, 2, 3, 4; e_i \neq e_j \).
As a result, when the state \( e_i (i = 0, 1, ..., 4) \) of the process \( \{X(t): t \geq 0\} \) is known at time \( \tau_n \), the time of its duration and the state \( e_i \) reached at time \( \tau_n \) do not depend stochastically on the process states taking place at times \( 0 = \tau_0, \tau_1, ..., \tau_n \), nor the time intervals of their duration.

The stochastic process \( \{X(t): t \geq 0\} \) is the process whose states are identical (constant) in intervals and the realisations of these states are continuous on the right. The lengths of the intervals \( [\tau_0, \tau_1), [\tau_1, \tau_2), [\tau_2, \tau_3), ..., [\tau_n, \tau_{n+1}), ... \) in which the process \( \{X(t): t \geq 0\} \) takes constant (the same) values are random variables with positive distributions. In case of the loads of the abovementioned engines we can assume [3] that the duration time of an arbitrary state \( e_i \in E_e \) (6), which was reached at time \( \tau_n \), do not depend stochastically on the states which earlier took place, nor the time intervals of their duration. Consequently, the process \( \{X(t): t \geq 0\} \) is the model of randomly changing main engine loads, with the set of states \( E_e = \{e_i; i = 1, 2, 3, 4\} \) can be interpreted as the process representing the duration time of the state \( c_i \) of the process \( \{X(t): t \geq 0\} \) on condition that the next state will be \( e_j \).

The specified states \( e_i \in E_e (i = 1, 2, 3, 4) \) of the process \( \{X(t): t \geq 0\} \) of an arbitrary main engine can be recognised using relevant diagnostic systems (SD), the applicability of which depends on the quality of the adopted diagnosing system (SDG) and its capability to recognise the states of the abovementioned engines as the diagnosed systems (SDN).

During the operation of an arbitrary diesel engine working as the main engine, changes of the states belonging to the set \( E_e = \{e_i; i = 1, 2, 3, 4\} \) can be interpreted as the process \( \{X(t): t \geq 0\} \) with the realisations constant (identical) in consecutive time intervals and continuous on the right [3, 7]. The lengths of the intervals in which the process \( \{X(t): t \geq 0\} \) takes the constant (identical) values are random variables \( T_i \) representing the time of duration of the state \( e_i \in E \) of this process, on condition that the next state is \( e_i \in E_e \), where \( i = 1, ..., 4 \) and \( i \neq j \). These variables are independent random variables with finite expected values \( E(T_i) \) and have positively concentrated distributions. Moreover, this process reveals a property consisting in the fact that the duration time of the state \( e_i \) which took place at time \( \tau_n \) and the state which started at time \( \tau_{n+1} \) do not depend stochastically on the states which took place earlier, nor the time intervals of their duration. Therefore we can assume that the future states (situations) depend solely on the presently existing situation. That means that the process \( \{X(t): t \geq 0\} \) is the semi-Markov process with the state change graph shown in Fig. 3. Defining this process requires defining its initial distribution \( P_i \) and the functional matrix \( Q(t) \).

The initial distribution of the process \( \{X(t): t \geq 0\} \) is the following:

\[
P_i = P[X(0) = e_i] = \begin{cases} 1 & \text{for } i = 0 \\ 0 & \text{for } i = 1, 2, ..., 3 \end{cases} \tag{4}
\]

According to the state change graph shown in Fig. 3, the functional matrix has the following form:

\[
Q(t) = \begin{bmatrix} 0 & Q_{01}(t) & 0 & 0 \\ Q_{10}(t) & 0 & Q_{12}(t) & 0 \\ 0 & Q_{21}(t) & 0 & Q_{23}(t) \\ 0 & 0 & Q_{32}(t) & 0 \end{bmatrix} \tag{5}
\]

The specified states \( e_i \in E_e \) can be interpreted as the state which started at the time \( \tau_n \) and the state which started at the time \( \tau_{n+1} \) do not depend stochastically on the states which took place earlier, nor the time intervals of their duration.

The stochastic process \( \{X(t): t \geq 0\} \) is the process whose states are identical (constant) in intervals and the realisations of these states are continuous on the right. The lengths of the intervals \( [\tau_0, \tau_1), [\tau_1, \tau_2), [\tau_2, \tau_3), ..., [\tau_n, \tau_{n+1}), ... \) in which the process \( \{X(t): t \geq 0\} \) takes constant (the same) values are random variables with positive distributions. In case of the loads of the abovementioned engines we can assume [3] that the duration time of an arbitrary state \( e_i \in E_e \) (6), which was reached at time \( \tau_n \), do not depend stochastically on the states which earlier took place, nor the time intervals of their duration. Consequently, the process \( \{X(t): t \geq 0\} \) is the model of randomly changing main engine loads, with the set of states \( E_e = \{e_i; i = 1, 2, 3, 4\} \) can be interpreted as the process representing the duration time of the state \( c_i \) of the process \( \{X(t): t \geq 0\} \) on condition that the next state will be \( e_j \).
The expected values $E(T_j)$ are related with the expected values $E(T_i)$ and the probability $p_{ij}$ in the following way:

$$E(T_j) = E(T_i) = \sum_j p_{ij} E(T_i), \quad i, j = 1, 4; \quad i \neq j \quad (11)$$

Therefore, according to the adopted interpretation of the internal combustion engine operation [2, 10], the main engine operation can be defined in the following general way, see (Fig. 4) and formula (7):

$$D[t_1, t_2] = \sum_j p_{1j} E(T_1) + \sum_j p_{2j} E(T_2) + \sum_j p_{3j} E(T_3) + \sum_j p_{4j} E(T_4)$$

The main engine operation defined by formula (12) takes place when we can assume that the changes of the propeller characteristic, resulting from changes of sailing conditions, do not affect considerably the changes of energy conversion in the engine working spaces, i.e. we can assume that the energy $E = \text{idem}$. When changes of the energy $E$ are larger and cannot be omitted, the formula (12) is to be modified by introducing the average value of this energy, which, as the random variable, is the statistics $E$. Then the operation will be defined in the following way:

$$D[t_1, t_2] = \sum_j p_{1j} E(T_1) + \sum_j p_{2j} E(T_2) + \sum_j p_{3j} E(T_3) + \sum_j p_{4j} E(T_4)$$

A more accurate definition of the operation requires introducing probabilities $P_j(j = 1, ..., 4)$ given by formula (20) to equations (12) and (13).

Particular probabilities $P_j(j = 1, ..., 4)$ have the following interpretations:

$$P_1 = \lim_{t \to E} P\{X(t) = e_1\}, \quad P_2 = \lim_{t \to E} P\{X(t) = e_2\},$$

$$P_3 = \lim_{t \to E} P\{X(t) = e_3\}, \quad P_4 = \lim_{t \to E} P\{X(t) = e_4\}$$

The probability $P_1$ can be interpreted as the probability of engine load according to the partial power characteristic, and the three remaining probabilities $P_2$, $P_3$, and $P_4$ can have similar interpretations referring to the operating power, nominal power, and maximal power characteristics, respectively.

Obtaining the (obviously approximate) values of the probabilities $P_j(j = 1, 2, 3, 4)$ requires valuating $p_{ij}$ and $E(T_i)$. Valuating the probabilities $p_{ij}$ and the expected values $E(T_i)$ is possible when we have the realisation $x(t)$ of the process $\{X(t); t \geq 0\}$ in a relatively long time interval of investigations, i.e. for $t \in [0, t_4]$, where $t_4 >> 0$. Then we can obtain numbers $n_{ij}(i, j = 1, 2, 3, 4; i \neq j)$, which represent the number of changes from the state $e_i$ to the state $e_j$ in the relatively long time.

The estimator of the highest likelihood of the probability of change $p_{ij}$ is the statistics: [7]

$$\hat{p}_{ij} = \frac{n_{ij}}{n_{ij}}, \quad i \neq j; \quad i, j = 1, 2, 3, 4 \quad (14)$$

the value:

$$\hat{p}_0 = \sum_j \sum_i n_{ij}$$

of which is the assessment of the unknown probability $p_{ij}$ of switching the process $\{X(t); t \geq 0\}$ from the state $e_i$ to the state $e_j$.

From the abovementioned realisation $x(t)$ we can also obtain realisations $x_{ij}^m$, $m = 1, 2, ..., n_i$, of the random variables $T_j$. The application of point estimation provides opportunities for easy assessment of $E(T_j)$ as the arithmetic mean of the realisation $x_{ij}^m$.

The expected value of energy in formula (12) is the observed value of the statistics $E_k(k = 1, 2, 3, 4)$. Obviously, this statistics is the random variable [1, 7] having the following general formula:

$$E_k = \frac{1}{n} \sum_{i=1}^{n} E_{ki} \quad (15)$$

where:

$E_{ki}$ – random variables having the same (arbitrary) distributions, with the same expected value $E(E_{ki}) = m_{ki}$ and variance:

$$D^2(E_{ki}) = \sigma_{ki}^2 \neq 0 \quad (16)$$

This way the random variable $E_k$ (statistics) is the arithmetic mean of $n$ independent random variables $E_{ki}$ having the same distributions. The expected value and the variance of the random variable $E_k$ are given by the relations [1, 14]:

$$E(E_k) = E_k = m_{ik},$$

$$D^2(E_k) = \frac{1}{n} D^2(E_{ki}) = \frac{\sigma_{ki}^2}{n}$$

It results from the Lindeberg-Levy theorem [1] that the random variable $E_k$ has the asymptotically normal distribution $N(m_{ik}, \sigma_{ki}/\sqrt{n})$ irrespective of the nature of the random variable $E_k$. That means that the arithmetic mean of $n$ independent random variables $E_{ki}$ having an arbitrary but the same distribution and the same expected value, $E(E_{ki}) = m_{ki}$ and the variance $D^2(E_{ki}) = \sigma_{ki}^2$, has the asymptotically normal distribution $N(m_{ik}, \sigma_{ki}/\sqrt{n})$.

Applying the proposed methodology to the analysis of energy changes during the main engine operation seems attractive due to the fact that the convergence of the distribution of the statistics $E_k$ to the normal distribution $N(m_{ik}, \sigma_{ki}/\sqrt{n})$ is very fast and we can use it for all $n \geq 4$, i.e. always in practice [1].

When the value $\sigma_{ki}$ is known, taking into account the distribution $N(m_{ik}, \sigma_{ki}/\sqrt{n})$ of the statistics $E_k$ we can calculate the confidence interval for the unknown expected value $m_{ik} = E(E_k)$ using the formula [1, 10]:

$$P\left\{\bar{e}_k - y_\alpha \frac{\sigma_{ki}}{\sqrt{n}} \leq E(E_k) \leq \bar{e}_k + y_\alpha \frac{\sigma_{ki}}{\sqrt{n}}\right\} = \beta \quad (17)$$

where:

$\beta$ – confidence level,

$y_\alpha$ – standardised variable of the normal distribution, which corresponds to the confidence level $\beta = 1 - \alpha$ ($\alpha$ - significance level),

$\bar{e}_k$ – value of the statistics $E_k$ which is the arithmetic mean of the performed measurements.

In experimental practice, as a rule, the value $\sigma_{ki}$ is not known, but it can be evaluated using the formula [1, 14]:

$$s_k = \sqrt{\frac{1}{n-1} \sum_{i=1}^{n} (E_{ki} - \bar{e}_k)^2} \quad (18)$$

Since the statistics $E_k$ has always the asymptotically normal distribution $N(m_{ik}, \sigma_{ki}/\sqrt{n})$ and its convergence to the normal distribution $N(\cdot, \sigma)$ is very fast, we can assume in practice that
the investigated energy $E_k$ has normal distribution $N(m_1, \sigma_1)$. It is noteworthy, however, that adopting the above assumption is not a limitation in experimental practice, as the statistics $E_k$ has always statistically normal distribution $N(m_1, \sigma_1/\sqrt{n})$. Moreover, the convergence of this distribution to the normal distribution is very fast [3]. Therefore the random variable:

$$\frac{E_k - E(E_k)}{\frac{s_k}{\sqrt{n-1}}}$$

has the t-Student distribution with $k = n - 1$ degrees of freedom [1, 10]. That means that the confidence interval for the unknown expected value $E(E_k)$ of the random variable $E_k$ can be calculated using the formula [1, 10]:

$$P\left\{ \bar{E}_k - t_{\alpha, n-1} \frac{s_k}{\sqrt{n-1}} \leq E(E_k) \leq \bar{E}_k + t_{\alpha, n-1} \frac{s_k}{\sqrt{n-1}} \right\} = \beta$$

(19)

In practice, the formula (19) is more applicable for assessing the energy changes during engine operation in real conditions of ship sailing than the commonly used formula (15), as it not only reflects the randomness of the results obtained in operating conditions, but also determines the error in estimating the expected value of the energy converted in the engine in its particular states. This error, which in the present case is equal to $1 - \beta$, is the not covering of the expected value $E(E_k)$ by the confidence interval given by the formula (19).

The application of the estimation in intervals makes it possible to determine the expected value $E(E_k)$ in the form of an interval with random limits, which means that the following inequality is to be fulfilled with probability $\beta$:

$$E_d \leq E(E_k) \leq E_g$$

(20)

It results from the inequality (20) that the main engine operation which can be considered safe can be assessed in the following way, according to formula (13):

$$D(t_1, t_2) = P_1 E_{1d}(T_1) + P_2 E_{2d}(T_2) + P_3 E_{3d}(T_3) +$$

$$P_4 E_{4d}(T_4) + P_5 E_{5d}(T_5) + P_6 E_{6d}(T_6) +$$

$$P_7 E_{7d}(T_7) + P_8 E_{8d}(T_8) + P_9 E_{9d}(T_9)$$

(21)

On the other hand, the optimistic engine operation can be assessed, according to formula (13), as:

$$D(t_1, t_2) = P_1 E_{1g}(T_1) + P_2 E_{2g}(T_2) + P_3 E_{3g}(T_3) +$$

$$P_4 E_{4g}(T_4) + P_5 E_{5g}(T_5) + P_6 E_{6g}(T_6) +$$

$$P_7 E_{7g}(T_7) + P_8 E_{8g}(T_8) + P_9 E_{9g}(T_9)$$

(22)

If necessary, processes of this type with a larger number of states $e_i, i = 1, 2, 3, \ldots, K$ can be investigated. Taking theoretically into account these needs, we can most generally discuss the process $\{X(t): t \geq 0\}$ with the set of states $E_{ak} = \{e_1, e_2, e_3, \ldots, e_K\}$. This process will be fully defined if, like in previous cases, a formula is given for the functional matrix:

$$Q_j = [Q_j(t)] \quad i = 1, 2, 3, \ldots, K$$

(23)

and its initial distribution has the form:

$$P_i = P\{X(0) = e_i\} = \begin{cases} 1 & \text{for } i = 1 \\ 0 & \text{for } i = 2, 3, \ldots, K \end{cases}$$

(25)

Consequently, $P\{X(0) = e_1\} = 1$.

Like in previous analyses, we have to assess the limiting distribution of the process [7]:

$$P_j = \frac{\pi_j E(T_j)}{\sum_{k=1}^{K} \pi_k E(T_k)}$$

(26)

Using the same procedure as in previous cases we arrive at the relation:

$$P_j = \frac{\prod_{k=2}^{j} \left(1 - \frac{p_{k-1,k-2}}{p_{kk-1}}\right) E(T_j)}{E(T_j) + \sum_{j=2}^{K} \prod_{k=2}^{j} \left(1 - \frac{p_{k-1,k}}{p_{kk-1}}\right) E(T_j)}$$

(27)

It results from formula (27) that, for instance, the probability of engine load resulting from the appearance of the state $e_1$ can be calculated as [7]:

$$P_1 = \frac{E(T_1)}{E(T_1) + \sum_{j=2}^{K} \prod_{k=2}^{j} \left(1 - \frac{p_{k-1,k-2}}{p_{kk-1}}\right) E(T_j)}$$

(28)

The presented considerations reveal that after adopting the interpretation of the operation in the here proposed version and making use of the theory of semi-Markov processes we can determine the operation of marine main engines in probabilistic formulation, which is more adequate than the deterministic formulation, as it reflects random conditions of operation of engines of this type.

**REMARKS AND CONCLUSIONS**

- The article presents the probabilistic method for evaluating the operation of an internal combustion engine used as the main engine on a ship. This method can be applied to an arbitrary piston internal combustion engine of both spark-ignition and compression-ignition type. The method takes it into account stochastic nature of energy conversion processes observed during engine operation. It was proved that a very useful model for investigating those processes is the model having the form of a stochastic process which is discrete in states and continuous in time. The analyses presented in the article reveal that this model can be the semi-Markov process which has the abovementioned features.

- The operation of the internal combustion engine was interpreted as generation of the required energy in a given time and its delivery (transmission) to the receiver. That means that when analysing the operation of these engines in given time and taking into account both the energy generated by these engines and time of its generation, we can compare (in a valuating formulation) this operation to a physical quantity which has a numerical value and the measure unit called joule-second [joule×second]. When analysing energy related qualities of internal combustion engines we should analyse their whole
operation, and not only their work, as the engine operation includes not only the energy conversion into work, but also into heat.

- The process of changes of energy states during the operation of an arbitrary diesel engine is a random process with continuous, positive and limited realisations.

- The models of changes of energy states may refer to the operation of an arbitrary engine, and include various numbers and interpretations of energy states. In each case, however, a model can be constructed in the form of a semi-Markov process, continuous in time and discrete in states, i.e. having a limited number of states.

- The developed semi-Markov model of the process of energy state changes during the main engine operation is the process with limited number of states and continuous in time.

Another approach to investigating the energy converted in the main engine and transmitted to the propeller screw was also proposed. This approach consists in considering this energy a random variable. The applicability of the Lindeberg-Levy theorem was proved which says that the statistics created based on the results of the investigations of a given energy is the random variable having the asymptotically normal distribution, irrespective of the nature of the random variable representing this energy. This enables using the estimation in intervals to evaluate the unknown expected value of the random variable, which can be the energy converted in the main engine and transmitted to the propeller screw during engine operation.

- The application of the estimation in intervals to the evaluation of engine operation has made it possible to assess its value in an optimistic version (22) and a safe version (21).

Comparing combined gas turbine/steam turbine and marine low speed piston engine/steam turbine systems in naval applications

Marek Dzida, Assoc. Prof.
Wojciech Olszewski, M. Sc.
Gdansk University of Technology

ABSTRACT

The article compares combined systems in naval applications. The object of the analysis is the combined gas turbine/steam turbine system which is compared to the combined marine low-speed Diesel engine/steam turbine system. The comparison refers to the additional power and efficiency increase resulting from the use of the heat in the exhaust gas leaving the piston engine or the gas turbine. In the analysis a number of types of gas turbines with different exhaust gas temperatures and two large-power low-speed piston engines have been taken into account. The comparison bases on the assumption about comparable power ranges of the main engine.

Key words: marine power plants, combined systems, piston internal combustion engine, gas turbine, steam turbine

INTRODUCTION

In recent years combined systems consisting of a gas turbine and a steam turbine have started to be used as marine propulsion systems. In inland applications the efficiency of these systems can exceed 60%. In naval applications such a system was used in Millenium, a passenger liner. But it is, so far, a unique case of propulsion system related with the highest efficiency. However, this system requires a more expensive fuel, which is the marine Diesel oil.

Another possible combined system can consist of a piston engine which cooperates with the steam turbine utilising the heat in the exhaust gas leaving the piston engine. The leading engine in this is system is always the piston internal combustion engine. The objects used as the main engines will be large low-speed piston engines which burn heavy fuel. At present, the efficiency of these engines reaches 45-50%. In case of such large main engine power ranges, the exhaust gas leaving the piston engine contains huge amount of heat which can be the object of further utilisation.

Another possible solution of a combined system which can be applied in shipbuilding consists of a gas turbine, and a steam turbine which utilises the heat leaving the gas turbine. This heat can be used for production of steam which, in turn, can be used in the steam turbine cycle.

CONCEPT OF A COMBINED SYSTEM

Combined propulsion systems in naval applications are first of all used in fast special ships and in the Navy as the systems being the combination of a Diesel engine and a gas turbine (CODAG, CODOG) or gas turbines (COGOG, COGAG). The propulsion applied in the passenger liner Millenium makes use of a COGES system which increases the efficiency and operating abilities of the ship by combining the operation of a gas turbine with a steam turbine which drives the electric generator, while the propeller screws are driven by electric motors. In this system the steam turbine cycle is fed with the steam produced in the waste heat boiler supplied with the exhaust gas from the gas turbines.

Fig. 1 shows sample efficiency curves of the combined gas turbine/steam turbine systems as functions of power plant load, as compared to the gas turbine working in a simple open cycle and the marine low-speed Diesel engine. The analysis of the efficiency changes reveals that the combined system composed of a gas turbine and a steam turbine has the highest efficiency, which can reach up to 60% for maximal loads. Gas turbines working in a simple open cycle have the lowest efficiency, of an order of 33÷35% on average, and about 40% as the maximum [7]. Low-speed Diesel engines reach efficiency of an order of 47÷50% [5, 6]. At the same time their efficiency characteristics as functions of load are flat, which is of highest importance in marine propulsion systems working in heavily changing load conditions. For instance, the relative efficiency drop \( \Delta n/n_{GT} \) is equal to 15÷20% when the load changes from 100% down to 50% in the combined gas turbine/steam turbine systems and gas turbines working in a simple cycle, while for a low-speed Diesel engine this efficiency drop is equal to 1÷2%.

This property of the Diesel engine and utilisation of additional heat contained in its exhaust gas makes the application of this
system very useful for marine propulsion systems working in extremely changing load conditions.

The temperatures of the exhaust gas from the gas turbines are equal to 450÷600°C on average, while for the low-speed Diesel engine these temperatures are of an order of 220÷300°C [5, 6], Fig. 2. But in the gas turbines this temperature remarkably decreases with decreasing load, while in the Diesel engine its changes are not high, nor monotonic: initially the temperature decreases and then starts increasing with the decreasing load.

This property of the Diesel engine in partial loads makes it possible to keep the temperature of the live steam at a constant level within a wide range of steam turbine cycle loads.

**Power evaluation of the combined propulsion system**

The power of the combined propulsion system is calculated by adding up particular power outputs of the system components, i.e. the main engine and the steam turbine:

\[ N_{\text{combi}} = N_C + N_{ST} \]  

(1)

while the efficiency of the combined system is:

\[ \eta_{\text{combi}} = \frac{N_{\text{combi}}}{m_f \cdot W_u} = \eta_D \cdot \left(1 + \frac{N_{ST}}{N_C}\right) \]

(2)

where:

- \( \eta_C, m_f \) – are the efficiency and mass flow rate of the main engine.

It results from the relation (2) that each additional power in the propulsion system increases the efficiency of the system and, consequently, decreases the fuel consumption. The higher the additional power obtained from utilisation of the heat contained in the main engine exhaust gas, the lower the fuel consumption. In these circumstances we should tend to reach maximal power also from the steam turbine, in which the power output largely depends on proper selection of live steam parameters and condenser parameters.

**Steam turbine cycle**

The combined cycle makes use of the waste heat in the exhaust gas from the Diesel engine or the gas turbine. Adding a steam cycle to the combined Diesel engine or gas turbine cycle makes it possible to increase the power of the combined system, i.e. increase the system efficiency according to formula (2).

In case of small powers and low live steam temperatures in combined systems, single pressure systems are used [1, 2, 3], Fig. 3. Such a system consists of a single pressure waste heat boiler, a condensing steam turbine, a water cooled condenser, and a single stage feed water preheater in the deaerator.

![Fig. 3. Flow diagram of a single pressure system](image)

**Steam turbine cycle**

The application of the single pressure system does not secure optimal utilisation of the energy in the exhaust gas when its temperature is high. The system which is most frequently used in these cases includes an additional low pressure evaporator [2, 3], Fig. 4, which not only increases the utilisation of the waste heat in the exhaust gas, but also provides opportunities for better thermodynamic use of the low-pressure steam.

![Fig. 4. Flow diagram of a two-pressure system](image)
Limits of steam cycle parameters

Limits of steam cycle parameters result from strength, technical, and durability conditions for particular system elements, but also from constructional and economic restrictions.

The temperature difference between the exhaust gas and the live steam was assumed equal to \(\Delta t = 10^\circ\text{C}\) in utilisation boilers used in shipbuilding, following the literature \[3, 4\]. The “pitch point” value recommended by MAN B&W \[4\] for marine boilers was assumed equal to \(\delta t = 10^\circ\text{C}\). The limit of the steam dryness factor \(x\) behind the steam turbine was assumed equal to \(x_{\text{limit}} = 0.86-0.88\). For marine condensers cooled with salt water, the company MAN B&W \[4\] recommends assuming the condenser pressure equal to \(p_K = 0.065\) bar. The temperature of the water which feeds the boiler is of high importance for the lifetime of the feed water heater in the boiler. MAN B&W \[4\] recommends assuming that the feed water temperature is not lower than \(120^\circ\text{C}\), when the content of sulphur exceeds 2%. The caloric value of the fuel was assumed constant and equal to \(W_u = 42700\) kJ/kg in the calculations.

Steam cycle optimisation

The combined systems, in this case the steam cycles, should make maximal use of the heat contained in the exhaust gas from the main engine. Therefore the optimisation is reduced to calculating steam cycle parameters for which the steam turbine reaches the maximal power output. The area within which optimal steam cycle parameters are searched for is to be narrowed to the area in which all above listed limits and restrictions imposed on the steam cycle are fulfilled.

In case of combined systems with gas turbines, a two-pressure steam turbine cycle is used. The calculations for the combined system with Diesel engines were performed for both the single- and the two- pressure variant. The steam turbine cycles in the combined systems were calculated based on the same schemes, and the same above listed assumptions and parameters.

### COMBINED GAS TURBINE/STEAM TURBINE SYSTEMS

In the calculations of the combined systems with gas turbines a number of types of gas turbines produced by Alstom and GE were taken into account. The analysed turbines represented different power outputs and different exhaust gas temperatures. The total power output of the gas turbines in the combined system was kept close to each other in all variants. The gas turbine parameters which were assumed in the calculations are collected in Table 1.

In this case the steam turbine system was analysed in the cycle with the two-pressure boiler, see Fig. 4, for the feed water temperature $t_{FW} = 120^\circ C$. The results of the combined cycle calculations are given in Table 2. The power output of the steam turbine with respect to that of the gas turbine changes between 35% and 49%. The power output of the steam turbine increases mainly due to the increase of the gas turbine exhaust gas temperature, but also depends on the ratio of the mass flow rate of the gas turbine exhaust gas to the turbine power output. The live steam pressure depends on the gas turbine exhaust gas temperature and increases with the increase of this temperature. The pressure $p_I$ of the low-pressure stage also increases with the increasing exhaust gas temperature ($t_4$), but this increase is not large.

The mass flow rates $m_d$ of the heating steam taken from the turbine extraction point for heating the condensate in the deaerator are relatively comparable. The mass flow rate $m_{IT}$ of the low-pressure steam which is passed from the boiler to the steam turbine decreases with the increasing temperature of the gas turbine exhaust gas.

The combined cycle applied to a system with the gas turbines makes it possible to increase the system efficiency by 35-49% with respect to the simple gas turbine cycle.

**COMBINED MARINE DIESEL ENGINE/STEAM TURBINE SYSTEMS**

The calculations of the combined Diesel engine/steam turbine systems took into account two marine low-speed engines: 9RTA96C made by Warstilsa [6] and 9K98MC made by MAN Diesel & Turbo [5] which revealed similar power outputs as the gas turbines. The analyses were performed in the combined system with the steam turbine cycle with a single pressure boiler, according to a scheme shown in Fig. 3, and the two-pressure boiler, see Fig. 4. The calculations were performed based on the producer’s data for the reference point according to ISO Conditions: ambient air temperature equal to 25°C and barometric pressure equal to 1 bar, Table 3.

In that case the steam turbine system was analysed for the feed water temperature equal to $t_{FW} = 120^\circ C$. The results of the combined cycle calculations are given in Table 4. Like for the combined system with gas turbines, the calorific value of the fuel was assumed equal to $W_u = 42700$ kJ/kg.

The power of the steam turbine in the combined system ranges from 5.3% to 6.8% of the piston engine power. The steam turbine power is larger for the steam turbine cycle with the two-pressure boiler, but this increase is not significant as compared to the power of the turbine with the single-pressure boiler. The turbine power increases with the increasing temperature of the piston engine exhaust gas. The pressure of the live steam for the two-pressure cycle is about 2.5 times as high as that for the single-pressure cycle and it increases with the increase of the temperature $t_4$ of the engine exhaust gas.

The live steam mass flow rate for the single-pressure system is larger than that for the two-pressure system. When related to the engine power, this parameter differs significantly for the two examined engines. The extraction steam mass flow rate $m_{t}$, as related to that of the live steam, is almost twice as small in the single-pressure system as in the two-pressure system. In the two-pressure system the mass flow rate $m_{t}$ of the low-pressure steam which feeds the steam turbine is equal to $59 \div 73\%$ of the live steam mass flow rate and increases with the increase of the piston engine exhaust gas temperature.

In the combined system the cycle efficiency increases by $5.6 \div 6.7\%$ with respect to the power plant with only a Diesel engine.

**COMPARISON OF COMBINED GAS TURBINE/STEAM TURBINE AND MARINE LOW-SPEED DIESEL ENGINE/STEAM TURBINE SYSTEMS**

The use of combined systems with the gas turbine or the Diesel engine cooperating with the steam turbine cycle increases the power of the system, and simultaneously increases the power plant efficiency.

In the systems with gas turbines the efficiency increase with respect to the simple gas turbine cycle ($35 \div 49\%$) is much larger than that observed in the combined cycle with the Diesel engine, the increase of an order of $5.5 \div 6.7\%$ with respect to the Diesel engine power, see Table 5.

The two combined systems reveal comparable overall efficiencies, and the resultant specific fuel consumption is also similar. It is noteworthy, however, that the heavy fuel burned in the marine low-speed engines is cheaper than the marine Diesel oil burned in gas turbines. This, in combination with comparable fuel consumption rates, results in lower fuel costs to the system with the gas turbine, and to $15\%$ and $11\%$ in the systems with the Diesel engine. The comparable levels of the stack losses for these two systems result from their comparable exhaust gas temperatures.

Other losses in the system with the Diesel engine amount to about $21\%$, as compared to $3\%$ in the systems with gas turbines. In the Diesel engine the other losses include the heat taken over in the scavange air coolers - about $15\%$, in the lubricating oil cooler – about $3\%$, and in the jacket water cooler $4\%$.

</table>

The exit temperatures $t_{\text{exh}}$ of the exhaust gas in the combined system for the cases with the gas turbine or the Diesel engine are comparable, Table 5.

Steam turbine cycles used in the combined system composed of gas turbines should include a two-pressure boiler, the least, to allow good utilisation of the energy of the high-temperature exhaust gas.

In the combined systems comprising a low-speed Diesel engine, a single-pressure boiler can be used in the steam turbine cycle, as it can secure good utilisation of the exhaust gas heat (much lower temperatures of the exhaust gas, compared to those recorded in the gas turbine).

The live steam parameters in the combined system with gas turbines are much higher than those in the system with the Diesel engine.

The power outputs of the steam turbines in the systems with gas turbines are many times higher than those in the systems with the Diesel engine, compare Tables 2 and 4. For comparable powers of the combined system, the power of the steam turbine amounts to $26 \div 33\%$ of the power of the entire power plant for the systems with the gas turbines, and to $5.3 \div 6.9\%$ in the systems with the Diesel engine. In those latter systems the power output of the Diesel engine amounts to $94\%$ of the power plant power, while in the systems with the gas turbines the power of the gas turbine amounts to $67 \div 74\%$. For the same total powers of the combined system the power of the Diesel engine is larger $1.3\times1.4$ times than that of the gas turbine.

The exit temperatures $t_{\text{exh}}$ of the exhaust gas in the combined system for the cases with the gas turbine or the Diesel engine are comparable, Table 5.
**FINAL CONCLUSIONS**

There is a possibility to use a combined system composed of the Diesel engine or a gas turbine as the leading engine, and the steam turbine cycle which utilises the heat contained in the engine exhaust gas. These systems reach thermodynamic efficiency comparable with the combined systems of gas turbines cooperating with steam turbines.

**Power outputs of the combined systems**

Depending on the adopted variant and main engine load, the use of the combined system can increase the power output of the power plant by 35 ÷ 49% in the systems with gas turbines, and by 5 ÷ 7% in systems with Diesel engines, with respect to a conventional power plant for the same fuel mass flow rate. Additional power output is generated due to recovery of the energy contained in the exhaust gas from the piston internal combustion engine or the gas turbine. This way the combined system reduces the specific fuel consumption by 26 ÷ 36% for cycles with gas turbines and by 5 ÷ 6.4% for the cycle with a Diesel engine, with respect to the conventional power plant.

**Efficiencies of the combined systems**

The use of the combined system for ship propulsion increases the system efficiency, which leads to the reduction of the specific fuel consumption and, additionally, increases the power of the propulsion system, without additional fuel consumption. Like the power output, the efficiency of the combined system increases with respect to the conventional power plant, reaching the level of about 43 ÷ 54% for maximal power outputs. The efficiency levels for the combined gas turbine/steam turbine and Diesel engine/steam turbine systems are comparable.

**Overall power plant dimensions**

The power plant with the combined system with gas turbines is smaller both in mass and dimensions than that with the Diesel engine.

**Economic aspects**

The technical and economic analysis of power plant operation should be performed to justify the use of such a power plant. The analysis should take into account both investment and operating costs. At comparable fuel consumption in both combined systems, the cost of burning the heavy fuel oil in the marine power plant with the Diesel engine is lower, as the combined systems with gas turbines burn more expensive marine Diesel oils. But in case of sailing in zones with limits imposed on heavy fuel burning, the use of a combined power plant with gas turbines can be more economically justified.

Depending on the adopted solution, the use of the combined power plant makes it possible to reach the assumed power of the propulsion system at smaller load of the main internal combustion engine, and to reduce the fuel consumption.

**NOMENCLATURE**

be – specific fuel consumption  
m – mass flow rate  
m_{fT} – mass flow rate of the low-pressure steam in the turbine  
N – power  
N_{C} – power of the gas turbine or of the piston internal combustion engine  
p – pressure  
p_{l} – low-pressure steam pressure  
t_{e} – temperature of the exhaust gas from the piston internal combustion engine or the gas turbine  
\eta – efficiency

**SUBSCRIPTS**

combi – combined system

ABSTRACT

The third part of the article presents a method for detecting failures of the automatic engine control system with the aid of an exhaust gas temperature setter, specially designed and machined for this purpose. It also presents a procedure of identifying the operating tolerances and determining the diagnostic tolerances for the exhaust gas temperature recorded in the naval turbine engine during the start-up and acceleration processes. The diagnostic tolerances were determined using the statistic inference, based on the hypothesis about the normal distribution of the starting exhaust gas temperature dispersion at the initial time of engine operation. The above hypothesis was verified using the non-parametric statistic test $\chi^2$ for examining the consistency of the empirical distribution with the assumed normal distribution. As a result of the examination, satisfactory convergence of the compared distributions was obtained which made the basis for assuming the three-sigma limits of the diagnostic tolerance for the analysed engine control parameter.

Key words: technical diagnostics; naval turbine engines; exhaust gas temperature; operating and diagnostic tolerances

INTRODUCTION

The general assessment of the technical state of a naval turbine engine can be done based on the values of basic parameters, such as power, specific fuel consumption, rotational speeds of rotating units, and/or mass flow rates of the delivered fuel or the thermodynamic medium flowing through the engine. All these parameters characterise, in a general way, the quality of engine operation [1, 2, 3, 6]. However, in case of most serial engines, the above parameters cannot be directly measured (their measurement is extremely complicated and/or economically unjustified) in conditions of engine operation in the naval power plant. Moreover, these parameters do not deliver sufficiently precise information on the real course of the physical processes taking place in basic functional modules of the engine (flow part, kinematic system, fuel installation, automatic control system, etc.) [4, 5, 7, 8, 14]. That is why the operational diagnostics of turbine engines makes use of a set of auxiliary control parameters which indirectly define the basic parameters and, additionally, provide opportunities for indicating the areas in which the largest energy losses are observed, as well as for identifying and localising known and recognisable failures of engine sub-assemblies and constructional elements during engine operation.

The real value of each control parameter differs from its calculated value, which results from differences in machining (inaccuracies of the realised technological process), the action of external agents (temperature, humidity, dust, vibrations, sea undulation, etc.), impurities, and/or wear and tear of constructional elements (reversible and irreversible changes of the surface layer) [7,8,9]. These actions are of random nature (random events) and, as a consequence, generate random changes of values of the structure parameters [2, 7]. Their effect on the technical state of the engine can also be observed as changes of the probability distribution of the occurrence of these parameters – the expected value and the average deviation (dispersion around the mean value for the set of engines in operation). The smaller the changes of the expected value and the mean deviation of the control parameter, the higher the correctness of engine operation and, consequently, its lifetime and reliability.

The correctness of operation of a constructional module or unit, as well as that of the entire turbine engine, is defined by the tolerances of parameters which reflect the most desirable and permissible courses of the realised physical processes:

- Operating tolerances (maximal permissible) - determined by the producer (designer) based on the tests done on prototype copies. They define precisely the maximum ranges within
which the values of the control parameters are to be kept
during the engine operation process to secure that the engine
performance parameters do not drop below permissible
levels, the engine operation is undisturbed and reliable,
and that the technical durability is good and in line with
the limits of the operating potential for particular hours and
days. When the value of any control parameter exceeds the
set operating tolerance limits, it is a signal of unacceptable
disturbance of energy conversion processes realised in the
engine, which threat with its failure (unstable operation of
the compressor, for instance) [3, 7, 8, 11, 12, 14].

• Diagnostic tolerances – determined via statistical inference
of the results of the tests done on a sufficiently numerous
set of new and correctly adjusted engines (revealing full
technical ability), compared with the results of operating
tests of the same engines is successive stages of their use,
provided that they still maintain a good functioning level,
which is assessed from changes of basic parameters.
During the time of engine operation the values of the control
parameters shift towards the diagnostic tolerance limits,
which signals the symptoms of small changes of engine’s
technical state, characteristic for the “approaching” state of
inability. At the same time, the above changes of the basic
parameters reflect the dependence of the technical state of
the engine on the time of its operation, which manifests
itself as changes of the expected values of the control
parameters and their average deviations.

Consequently, a conclusion can be formulated that the
tolerances of the control parameters for diagnostic purposes
should be much smaller (more restrictive) that the operating
tolerances.

IDENTIFYING FAILURES OF THE
AUTOMATICS SYSTEM (OPERATING
TOLERANCES)

Some most typical operating failures of the engine
automatics system can be identified using simulation analyses
done with the aid of specially designed setters (testers) on
the non-operating engine [15]. These devices control the
correctness of operation of the engine protection system against
the excessive increase of the exhaust gas temperature. The tests
aim at checking correct threshold settings for the (maximal)
exhaust gas temperatures behind the exhaust gas generator, and
the temperature grow rates at which the final control units in
the automatics system open:
- the fuel overflow valve (ZPP),
- the main fuel valve (ZGP),
- the immediate (emergency) engine switch-off valve
(ZA).

The values determined in the above way are considered the
limits of the operating tolerance zone for permissible changes
of parameters in the process of engine start-up and acceleration.
Sample results of these tests are shown in Fig. 1 in the form of
simulated dynamic time-histories of exhaust gas temperature
changes. To assess the ability of the examined engine, the time-
histories obtained from the simulation test are compared with
the real curves recorded during earlier start-ups (see: part II –
Unsteady states).

The comparison analysis of the results recorded during the
many years of operation of the UGT type ZORYA naval engines
which were the object of diagnostic supervision [15] has made
it possible to recognise characteristic thresholds for initiating
certain actions of the protection system. These thresholds are
considered the limits of the operating tolerance zone for the
time derivative of the averaged exhaust gas temperature behind
the exhaust gas generator:
• \( \frac{dT_{eg}}{d\tau} > 80 \text{ K/s} \) – the engine is automatically switched-off
  - ZPP(+), ZGP(+), ZA(+);
• \( \frac{dT_{eg}}{d\tau} > 50 \text{ K/s} \) – the engine can be started with
  automatic fuel dosage - ZPP(+), ZGP(+), ZA(-);
• \( \frac{dT_{eg}}{d\tau} < 50 \text{ K/s} \) – the engine is starter automatically
  without the action of the protection system - ZPP(+), ZGP(-),
  ZA(-).

Having analysed the data shown in Fig. 1 we can conclude
that the system of thermal engine protection is out of order in
this case. The fuel overflow valve (ZPP) does not work,
irrespective of the rate of exhaust gas temperature grow (curves
1 and 2). After a detailed analysis of the recorded symptoms
of engine inability, the damaged engine automatics elements were
localised and replaced. The next simulation tests confirmed the
correctness of the formulated diagnosis, which is illustrated in
Fig. 1 by the line 3 recorded after removing the defect.

It also results from the performed tests that the system
has the zone of insensitivity ranging between 273 and 593 K,
irrespective of the dynamics of exhaust gas temperature
grow.

METHOD OF DEFINING DIAGNOSTIC
TOLERANCES

Measurements of the control parameters which characterise
the quality of the turbine engine operation in the processes
of start-up, acceleration and deceleration of rotor units, the
operation at steady-load ranges, and the engine switch-off are
done in the very initial stage of engine use, directly after its
installation in the power plant room [14, 15]. Discrete values
of the diagnostic parameters recorded in these measurements are modelled as continuous and one-dimensional random variables with the certain probability distribution, expected value, and variance being the measure of the dispersion of the measured results. In this situation the diagnostic tolerance calculation method is mainly limited to finding the form of the distribution of the observed discrete values of the diagnostic parameter around the average value for the entire population of engines in operation, and then to determining the parameters of this distribution. One of methods making use of the statistic inference to find the form of the distribution of the random variable consists in verifying the hypothesis that the examined distribution of the discrete values of the diagnostic parameter can be approximated using an assumed theoretical distribution which is described by a known random variable probability density function at time \( t = 0 \) [2, 10]. Once the form of the function of the theoretical distribution and its characteristic parameters (the expected value \( m \) and the average deviation \( \sigma \)) are known, we can determine the interval of tolerance for the values of the diagnostic parameters, for instance \( m \pm 3\sigma \) for the normal distribution.

A method for determining the limits of the diagnostic tolerance zone for the rate of growth of the exhaust gas temperature behind the exhaust gas generator in the start-up process\(^1\), which take into account the unrepeatability of production and the effect of external operating agents, will be demonstrated on the population of 46 UGT3000 type Zorya turbine engines which were introduced to operation in naval power plants [14,15]. Table 1 collects a set of realisations of the numerical values of the starting temperatures recorded in the start-up process of the new engines (or directly after general overhaul) in the state of full technical ability (the values are reduced to normal atmospheric conditions) [3, 13].

Tab. 1. Set of realisations of numerical values of the starting temperature \( \frac{d(T_{ex})}{dt} \) (random variable \( X(t) \)) recorded during the start-up in the initial time of operation of UGT3000 engines installed in naval power plants

Assuming that the distribution of the values of the analysed diagnostic parameter in time \( t = 0 \) is normal, which is confirmed by diagnostic tests of aircraft engines [2], a zero hypothesis \( H_0 \) is formulated that the distribution function of the empirical distribution shown in Table 1 is consistent with the normal distribution function. The zero hypothesis was verified using the non-parametric statistical test \( \chi^2 \), which does not require the information on normal distribution parameters, i.e. the expected value \( m \) and the variance \( \sigma^2 \) [10]. In this situation the statistical estimation of the expected value and the variance for the calculated statistics is made based on the arithmetic mean \( \bar{x} \) and the standard deviation \( \bar{\sigma} \) of the measured results.

For testing purposes, the interval within which the values of the random variable are included \( X(t) = \{x_i\} \) was divided into six equal sub-intervals of 3.0 K/s in length (the widths of the intervals do not have to be equal) – Table 2. The limits of the intervals were chosen in such a way that the numbers of the results of measurement in successive intervals were not excessively small (5-8 results in each interval as the minimum).

* arithmetic mean \( \bar{x} = 18.97826 \), * standard deviation \( \bar{\sigma} = 3.784919 \)

\(^1\) Further in the text, more briefly referred to as the “starting temperature”.

POLISH MARITIME RESEARCH, No 4/2011 51
If the number of the results of measurement in the interval is smaller than 5, this interval is to be linked with one of the neighbouring intervals [10].

In successive steps we calculate:

- the normalised limits of the intervals with respect to \( \bar{x} \), recalculated to \( \sigma \) units:
  \[
  z_i = \frac{x_i - \bar{x}}{\sigma}
  \]
  (1)

The beginning of the first interval is \(-\infty\), while the end of the last interval is \(+\infty\). The end of the previous interval is simultaneously the beginning of the next interval;

- the normalised Laplace function of the normal distribution for the beginnings \( \Phi_p(z_i) \) of the intervals – from statistical tables [10];
- the theoretical probability to obtain the result from the \( i \)-th interval:
  \[
  p_i = \Phi_p(z_{i+1}) - \Phi_p(z_i)
  \]
  (2)
- the theoretical number of results in the \( i \)-th interval: \( n \cdot p_i \);
- the \( \chi^2 \) statistics for each interval:
  \[
  \chi_i^2 = \frac{(n_i - n \cdot p_i)^2}{n \cdot p_i}
  \]
  (3)

The last step includes calculating the value of the statistics for the analysed set of random variable realisations:

\[
\chi_0^2 = \sum_{i=1}^{n} \chi_i^2 = 2.8012
\]
(4)

The calculated value of the \( \chi_0^2 \) statistics should be compared with its critical value determined from the statistical tables [10], at the assumed significance level \( \alpha = 0.05 \) and the number of freedom degrees \( f \) calculated from the following relation:

\[
f = l - k - 1
\]
(5)

where:

\( l \) – number of intervals in the distributive series,

\( k \) – number of estimated parameters of the verified distribution.

Two parameters characterising the normal distribution: \( \bar{x} \) and \( \sigma \), were evaluated based on the empirical data. For the number of degrees of freedom: \( f = 2 \) (\( l = 5 \), \( k = 2 \)) and the assumed significance level: \( \alpha = 0.05 \) the critical value of the statistics which was read in the \( \chi^2 \) distribution tables is equal to \( \chi_0^2 = 5.991 \) [10].

The calculated value of the statistics is equal to \( \chi_0^2 = 2.8012 \) and is smaller than the critical value \( \chi_{f}(\alpha = 0.05, f = 2) = 5.991 \). That means that there is no ground for rejecting the hypothesis and, consequently, that the analysed empirical distribution can be considered consistent with the normal distribution. Therefore the probability density function of the random variable \( X(t) = \{x_i\} \) in the initial operation stage (time \( t = 0 \)) can be given by the formula:

\[
f(x) = \frac{1}{\sigma \sqrt{2\pi}} \exp\left[ -\frac{(x - \bar{x})^2}{2 \cdot \sigma^2} \right]
\]
(6)

Having known the formula for the distribution and its basic parameters we can calculate the limits of the diagnostic tolerance zone assuming the value interval \( m \pm 3\sigma \) as the diagnostic limiting conditions for the control parameter of interest. For the analysed starting temperature the calculated expected value was equal to \( m = \bar{x} = 18.98 \) K/s and the average deviation was \( \sigma = \bar{\sigma} = 3.78 \) K/s, which gives the following diagnostic tolerances of the analysed control parameter:

\[
7.64 \leq X_{t=0} \leq 30.32
\]
(7)

It results from the performed calculations that the diagnostic tolerances of the rate of exhaust gas temperature grow in the start-up process of the turbine engine of UGT3000 type are limited from one side, which means that the limiting value of this parameter assessed for diagnostic purposes must not exceed 30 K/s in a new engine.

Taking advantage, in turn, of the symmetry of the normal distribution and the values of the Laplace function \( \Phi_p(z) \) we can calculate the probability that the random variable \( X(t) \) takes a value from within this interval:

\[
P(X \in (m \pm 3\sigma)) = \Phi_p(3) - \Phi_p(-3) = 0.9973
\]

Thus, assuming the three-sigma limits for the diagnostic tolerances of the analysed control parameter means that less than \( 3 \% \) of possible results of measurement differ from the expected value by more than \( 3\sigma \).

In the process of engine operation on a ship, the action of unfavourable operating agents leads to ageing, wear, and pollution of constructive elements. These processes are permanent and irreversible, and they always accompany the operation of internal combustion engines in marine conditions. All this leads to the decrease of the usable potential, the measure of which are the deformations of the shape of probability density function defined by the changes of the expected value and the average deviation, while the normal distribution of the random variable (dispersion of the analysed control parameter) is still being preserved. As a consequence, the dispersion of the exhaust gas temperature grow rate in the engine start-up process increases, and the limits of the diagnostic tolerances, which under no circumstances can exceed the operating tolerances, become wider – Fig. 2. We accept that with the increasing total time of engine operation its functioning is getting less correct, but still preserves all requirements of safe use.

\[\text{Fig. 2. Deformations of the shape of the probability density function for the analysed random variable vs. the total time of operation of the turbine engine}\]

It results from the numerical data shown in Fig. 1 that after calculating the shapes of the probability density function of the random variable in successive stages of engine operation (for instance, in annual control and measurement cycles, or after each 500 hours of operation) we can determine the trend lines for the changes of the expected value and the upper tolerance limit of the set or realisations of the diagnostic parameter. We can also assess the horizon for the prognosis of correct engine operation (without failures) until time \( t_{eg} \) based on the crossing point of the line of upper diagnostic tolerance limit with the line of the operating tolerance limit. For this purpose the value
of the diagnostic parameter is to be measured on the examined engine - for instance, the point:

\[ x_{t=\text{leg}1} = \left( \frac{dT_{\text{t}}}{dt} \right)_{t=\text{leg}1} \]

and the upper diagnostic tolerance limit is to be extrapolated until it crosses the line of the operating tolerance limit (time \( t_{\text{eg2}} \)) etc. This way we formulate the strategy of engine operation based on its current technical state, the reconstruction of which (adjustment, repair, replacement of an element) depends on individual features of constructional structure degradation, mainly connected with the nature of changes of engine load (number of start-ups, stop-down, accelerations and decelerations of rotor units, manoeuvres of the separate power turbine, etc.).

**CONCLUSIONS**

The presented sample application of the statistical method for determining the diagnostic tolerances of the rate of grow of the exhaust gas temperature recorded in the start-up process of a naval turbine engine can be extended onto remaining control parameters recorded during engine operation. A necessary condition for statistical inference is to adopt the assumption that in the initial stage of operation the examined engines maintain correct functioning, which is assessed from the values of basic parameters. In this situation the value of the observed control parameter shifts towards the limit of the diagnostic tolerance zone, thus generating a symptom of small changes of the technical state, characteristic for the “approaching” inability state. Simultaneously it reflects the dependence of the technical state of the engine on the time of its use, which manifests itself by changes of the expected values of the control parameter and its average deviations in successive engine operation stages.

Influence of pitting corrosion on strength of steel ships and offshore structures

Marek Jakubowski, Assoc. Prof.
Gdansk University of Technology

ABSTRACT

The present paper deals with the influence of pitting corrosion on mechanical properties of mild and low alloy steels and strength of steel structures under static and quasi-static loads. Pitting corrosion is a very important phenomenon that influence local strength of ship hull members. The present paper is based mainly on Japanese publications. Analyzing the standard tensile diagrams one can see that that pitting corrosion reduces the load corresponding to yield stress (YS) and, even more markedly, tensile strength UTS, reduces almost to zero plastic flow strains at YS load level and dramatically reduces the total elongation to fracture. Nominal UTS load for uniformly corroded specimens is higher than that for pitted specimens at the same average thickness loss. The strength related to the true fracture surface area (i.e. reduced by pits, taking into account real path of the crack through the pits) is almost independent of the thickness loss and is almost the same as for uniform thickness loss. For wide specimens the tensile strength depends mainly on the local deformation ability, and the maximum loading ability for large members, predicted on the base of the total true fracture surface area, can be overestimated. Concept of equivalent thickness loss for plates under bending and compression and for more complex structural models as well as relation between the average and the equivalent thickness losses has been presented. Approach based on degree of pitting (ratio of pitted area to total plate surface area) has been shown as a real and more convenient than the approach based on the thickness loss.

Keywords: pitting corrosion, strength, shipbuilding steels, ship structures

INTRODUCTION

There are two groups of actions that can lead to damages of real structures:
- Chemical or electrochemical, if undesirable, are identified with corrosion
- mechanical, usually identified with stresses or strains

Interaction of corrosive and mechanical factors is the most general case. Almost all corroding structures are stressed. Almost all stressed structures are exploited in any environment that is not neutral in mechanical damage process. Pure mechanical or pure corrosive damage can be considered as specific and unusual cases. In case of vacuum or eventually inert gas environment we can assume that damage is purely mechanical in nature, while for very low stress levels we can assume that damage is purely corrosive.

The above is especially true for ships and offshore structures that are the main object of the present paper. Corrosive environment of these structures is also the main source of service loads, i.e. static or dynamic pressure of sea water.

The present paper concerns the influence of pitting corrosion on strength of steels and steel structures under static or quasi-static loads. The mild and low alloy steels used for welded marine structures are considered as insensitive to stress corrosion cracking in marine environment. Therefore only the pit nucleation and growth process should be considered as a complex mechanical-electrochemical phenomenon. Fracture process occurs in a relatively short time and influence of corrosive environment on this process can be considered as negligible. Pitting corrosion incubation and growth and the role of strain and/or stress in this process has been discussed elsewhere [1, 2]. The present paper is focused on the influence of pre-existing pits on mechanical properties of mild and low alloy steels and strength of the steel structures.

Previous pitting corrosion influences the fatigue strength and life by the following ways:
- I reduction of the average material thickness that influence the nominal stress in the structure;
- II pitting-corrosion-induced roughness of the material surface that leads to local stress concentrations at some locations at the surface.
The role of pitting in fatigue of materials and structures is commonly appreciated. The problem has been discussed in [2] on the wide base of references concerning different materials. In common opinion, pits, if they are present at the material, are almost always the potential sites of the fatigue crack initiation, thus they reduce the fatigue life. If strength of steel structures under static or quasi-static loadings is considered, the opinion is not so unanimous.

Melchers [3] has formulated opinion that pitting corrosion has very little influence on the strength of well maintained structures, such as ships – general corrosion (loss of thickness) is more important. This opinion has been accepted by Wang et al. [4]. These authors have elaborated models for the time-related growth of the maximum depth of pitting because, in their opinion, the main menace is perforation of the structure walls and it can be dangerous especially for pipelines and tanks. However, extensive studies of the influence of pitting corrosion on the behaviors of materials and structures under static loading has been carried out in Japan by Nakai, Matsushita, Yamamoto and, in some papers, Arai [5 - 10], and they have shown that the influence of pitting on the steel strength is not negligible. General strength of ship hull is mainly affected by general corrosion that reduce thickness of shell and stiffeners therefore reduce midship section modulus. Pitting corrosion is a very important phenomenon that influence local strength of ship hull members.

International Association of Classification Societies (IACS) [11, 12] and Polish Register of Shipping (PRS) [11, 12] have defined the required minimum thickness of plating in pits or other local corrosion areas (is to be greater than 70-75% of the as-built thickness), or average thickness across any cross section in the plating (is to be greater than the renewal thickness for general corrosion). These requirements are surely based on unknown considerations of strength of pitted steel.

**TENSILE DIAGRAM FOR PITTED STEEL**

The mentioned Japanese authors tested only conical pits that are observed on hold frames of bulk carriers. The pits were generated artificially by spot drilling of the both steel surfaces. Different pit patterns were manufactured with different values of degree of pit intensity DOP (ratio of pitted area to entire area of the specimen). In the Rules of Classification Societies DOP is called simply the pitting intensity. In order to verification of validity of such artificial pits testing, the results were compared to the results for actually corroded specimens [9]. It has appeared that specimens with orderly located artificial pits which had a fixed diameter equal to the average pit diameter in actual corroded specimens could simulate the actual corroded specimen where the pit size and distribution are random. Results of standard static tensile tests of pitted and smooth specimens are described in [6, 7, 9]. Exemplary tensile diagrams (load versus displacement) for small specimens are shown in Fig. 1 [7]. It is evident that pitting:

(i) reduced the load corresponding to yield stress;
(ii) reduced almost to zero plastic flaw strain at the level of yield strength;
(iii) reduced load, corresponding to ultimate tensile strength, even stronger than yield stress;
(iv) markedly reduced total elongation to fracture;
(v) total elongation for 13mm and 11mm uniformly thick specimens is the same.

The same investigations [7] have shown that the effect of pitting depends on the specimen thickness, i.e. the nominal tensile strength and total elongation dropped more significantly for higher pit-depth-to-plate-thickness ratios. For thinnest plated (10 mm) total elongation dropped from 30% to about 5%.

Matsushita et al [6] realized tensile tests of specimens with different DOP from a single one-side pit up to more than 80% of two-side surfaces covered by pitting. Pitting corrosion causes not only unevenness of the material surface but reduction of the average thickness too. The larger DOP leads to the larger average thickness loss. Results are plotted as a function of the thickness loss in Fig. 2 and Fig. 3.

Trend lines for ideally uniform corrosion are also plotted in Fig. 2. All over the range of thickness loss values, the nominal strength for pitted specimens is lower than for “uniformly corroded” ones. The specimens fractured at the smallest area where the local thickness reduction was larger than the average value. Meanwhile, strength of the “uniform corrosion” specimen with a value of uniform thickness loss is always compared with the pitted specimen strength of the same average (not local) thickness loss. True fracture surface does not develop close to one surface approximately perpendicular to load axis, as that in non-pitted specimens, but jumps from one plane to another according to pits distribution. True fracture surface area can be evaluated as the area of the fracture surface before loading projected to the plane perpendicular to the load axis and practically can be substituted by the minimum cross-sectional area (i.e. locally reduced by pits) before loading perpendicular to the load axis [9]. In Matsushita et al opinion, the true strength that is based on the true fracture surface area is the same for uniform and non-uniform thickness loss (Fig. 2b). In our opinion, however, the above explanation is only partially valid. If the only specimen of another type (wide specimen – type B) is not taken into account, the strength of pitted specimens for average thickness loss below 2 mm will be 527-600 MPa, while for average thickness loss above 2 mm

---

**Fig. 1. Results of small tensile specimens testing:**

(a) view of specimens after testing; (b) tensile diagram "load – displacement" [7]
the strength will be 400-527 MPa thus it is not independent of the intensity of pitting. In spite of that, the maximum load that can be carried by a specimen can be approximately predicted by the above approach based on true fracture surface or minimum cross-sectional area [6, 9].

The last conclusion concern so called small specimens. The situation is more complex in case of large (much more wide) specimens. Fracture of small specimen occurs when plastic deformation develops throughout the minimum cross section. In much more wide specimens, having areas with pits of different size and distribution, the deformation ability differ from location to location. As a result, fracture occur locally at this regions where elongation reaches critical value first, i.e. where the elongation ability is the lowest due to local pits sizes and distribution, this local fracture is the dominant factor that determines the maximum load ability of the specimen modeling a structural member [9]. That is why the maximum loading ability for large members, predicted on the base of true fracture surface or minimum cross-sectional area, is overestimated, while for small members this approach was successful [10].

Analogous diagram for total elongation is shown in Fig. 3. The uniform thickness loss does not cause reduction of total elongation (see also Fig. 1). Thus the observed very significant drop of values of total elongation has to be entirely attributed to non-uniform character of pitting corrosion. The drop is very rapid for small values of thickness loss (also values DOP are small). Then relationship saturates and the total elongation does not depend on thickness loss or maximum pit depths are not always dominant factors for ultimate strength but the strength depends also on type of pit distribution on the both sides of the plate [5, 9].

Nakai and co-workers analyse equivalent thickness of plate for ultimate tensile strength (te) that is defined as the thickness of an uniformly corroded plate whose ultimate strength is the same as that of pitted plate. Value of the equivalent thickness is almost independent of the loading mode: from pure compression, through different combinations of compression and bending, up to pure bending [5]. Nakai and co-workers have compared these values of equivalent thickness to the values evaluated by tensile test, where the following proportion is valid:

$$t_e/t_0 = \sigma_u/\sigma_{u0}$$

(1)

where te is the original plate thickness, $\sigma_u$ and $\sigma_{u0}$ are the nominal UTS for the plate with and without pits, respectively. The comparison has been made for the same degree of pit intensity (DOP). It has appeared that equivalent thickness evaluated in tensile test of pitted specimens is smaller than that for evaluated for plates subjected to in-plane compression and bending, especially for the thinnest specimens. Thus tensile test represent the most dangerous case. If an evaluation method for the effect of pitting corrosion on the equivalent thickness (te) under tensile loading is established, a reduction of te of pitted plates is smaller than or equal to that of uniformly corroded plate for the same average thickness loss. There is a tendency for the strength reduction to increase as the pit diameter and depth is increased. Thus a prediction of the strength of pitted plates using the average thickness loss would lead to non-conservative results. However, the average thickness loss or maximum pit depths are not always dominant factors for ultimate strength but the strength depends also on type of pit distribution on the both sides of the plate [5, 9].

As for tensile test, for these loads it also has appeared that ultimate strength of pitted plates is smaller than or equal to that of uniformly corroded plate for the same average thickness loss. There is a tendency for the strength reduction to increase as the pit diameter and depth is increased. Thus a prediction of the strength of pitted plates using the average thickness loss would lead to non-conservative results. However, the average thickness loss or maximum pit depths are not always dominant factors for ultimate strength but the strength depends also on type of pit distribution on the both sides of the plate [5, 9].

Nakai and co-workers analyse equivalent thickness of plate for ultimate tensile strength (te) that is defined as the thickness of an uniformly corroded plate whose ultimate strength is the same as that of pitted plate. Value of the equivalent thickness is almost independent of the loading mode: from pure compression, through different combinations of compression and bending, up to pure bending [5]. Nakai and co-workers have compared these values of equivalent thickness to the values evaluated by tensile test, where the following proportion is valid:

$$t_e/t_0 = \sigma_u/\sigma_{u0}$$

(1)

where te is the original plate thickness, $\sigma_u$ and $\sigma_{u0}$ are the nominal UTS for the plate with and without pits, respectively. The comparison has been made for the same degree of pit intensity (DOP). It has appeared that equivalent thickness evaluated in tensile test of pitted specimens is smaller than that for evaluated for plates subjected to in-plane compression and bending, especially for the thinnest specimens. Thus tensile test represent the most dangerous case. If an evaluation method for the effect of pitting corrosion on the equivalent thickness (te) under tensile loading is established, a reduction of te of pitted plates is smaller than or equal to that of uniformly corroded plate for the same average thickness loss. There is a tendency for the strength reduction to increase as the pit diameter and depth is increased. Thus a prediction of the strength of pitted plates using the average thickness loss would lead to non-conservative results. However, the average thickness loss or maximum pit depths are not always dominant factors for ultimate strength but the strength depends also on type of pit distribution on the both sides of the plate [5, 9].

As for tensile test, for these loads it also has appeared that ultimate strength of pitted plates is smaller than or equal to that of uniformly corroded plate for the same average thickness loss. There is a tendency for the strength reduction to increase as the pit diameter and depth is increased. Thus a prediction of the strength of pitted plates using the average thickness loss would lead to non-conservative results. However, the average thickness loss or maximum pit depths are not always dominant factors for ultimate strength but the strength depends also on type of pit distribution on the both sides of the plate [5, 9].

Nakai and co-workers analyse equivalent thickness of plate for ultimate tensile strength (te) that is defined as the thickness of an uniformly corroded plate whose ultimate strength is the same as that of pitted plate. Value of the equivalent thickness is almost independent of the loading mode: from pure compression, through different combinations of compression and bending, up to pure bending [5]. Nakai and co-workers have compared these values of equivalent thickness to the values evaluated by tensile test, where the following proportion is valid:

$$t_e/t_0 = \sigma_u/\sigma_{u0}$$

(1)

where te is the original plate thickness, $\sigma_u$ and $\sigma_{u0}$ are the nominal UTS for the plate with and without pits, respectively. The comparison has been made for the same degree of pit intensity (DOP). It has appeared that equivalent thickness evaluated in tensile test of pitted specimens is smaller than that for evaluated for plates subjected to in-plane compression and bending, especially for the thinnest specimens. Thus tensile test represent the most dangerous case. If an evaluation method for the effect of pitting corrosion on the equivalent thickness (te) under tensile loading is established, a reduction of te of pitted plates is smaller than or equal to that of uniformly corroded plate for the same average thickness loss. There is a tendency for the strength reduction to increase as the pit diameter and depth is increased. Thus a prediction of the strength of pitted plates using the average thickness loss would lead to non-conservative results. However, the average thickness loss or maximum pit depths are not always dominant factors for ultimate strength but the strength depends also on type of pit distribution on the both sides of the plate [5, 9].

As for tensile test, for these loads it also has appeared that ultimate strength of pitted plates is smaller than or equal to that of uniformly corroded plate for the same average thickness loss. There is a tendency for the strength reduction to increase as the pit diameter and depth is increased. Thus a prediction of the strength of pitted plates using the average thickness loss would lead to non-conservative results. However, the average thickness loss or maximum pit depths are not always dominant factors for ultimate strength but the strength depends also on type of pit distribution on the both sides of the plate [5, 9].
Equivalent thickness loss \((t_{el})\) is defined as thickness loss of uniformly corroded plate that has the same tensile strength as a plate with pitting corrosion. It can be calculated by:

\[
t_{el} = t_{0} - t_{e} 
\]

Average thickness loss \((t_{av})\) of pitted plates is defined by:

\[
t_{av} = t_{0} - t_{ave} 
\]

where:

\(t_{ave}\) – the average thickness of the pitted plates.

Finite Element (FE) analyses of pitted square plates under uniaxial compression, biaxial compression, shear and combinations if the above mentioned loadings showed that the equivalent thickness can conservatively be predicted by equation (3) and the following equation [10]:

\[
t_{cl} = 1.25 \cdot t_{el} 
\]

Thus ultimate strength of pitted plate of an average thickness \((t_{av})\) is lower than the strength of uniformly corroded plate of the same thickness. This means that unevenness of the plate surface due to pitting corrosion reduce ultimate strength of the plate.

FE analyses of structural model: beam (web plate, face plate and shell) under 4-points bending has been done [10]. Web plates were pitted. It has appeared that for the following cases: (i) the ultimate strength is reached accompanying local buckling; (ii) the structural models collapse without buckling; (iii) shear buckling of web plates occurs; and (iv) web crippling occurs, equivalent thickness of the web plates can be predicted by equation (3) and the following equation:

\[
t_{cl} = 1.44 \cdot t_{el} 
\]

The above equations mean that the influence of the pitting-corrosion-induced unevenness of the plate surface on the ultimate strength of more complex structural models is more detrimental than for simple square plates.

**APPROACH BASED ON DEGREE OF PITTING (DOP) INSTEAD THICKNESS LOSS**

Nakai and co-workers conclude that for non-uniform random pitting, the average thickness loss of a whole plate, or for the minimum cross section, is often difficult to determine. Each pit is covered with a heavy rust blister which is difficult to remove, even with hammers. Even if the rust blisters and rust from non-pitted areas are removed, correct thickness measurement is difficult due to great unevenness of the surface. [9, 10]. The average thickness loss or the average thickness loss at the minimum cross section cannot be determined directly by observation of the plate surface. Meanwhile, degree of pitting (DOP) can be approximately evaluated by observation of the plate surface also without removing the heavy rust blisters, because Nakai and co-workers has shown that the diameter of the rust blisters and that of the corresponding pits are almost the same [10] and degree of blisters intensity (ratio of the surface area covered with rust blisters to the entire surface area) corresponds to DOP. Therefore, to elaborate a method of evaluating the tensile strength of pitted members using the value of DOP, is a task of primary importance.

First attempt to solve this problem has been made by the same authors [10]. Diagrams of thickness loss of plates versus values of DOP are shown in Fig. 4. The diagrams include average thickness loss \(t_{av}\) and effective thickness loss \(t_{e}\) for ultimate strength calculated for different cases: square plates under combined loading of compression and shear [equation (5)], more complex structural models (equation (6)) and for ultimate tensile strength. From ultimate-strength point of view, average thickness loss is not so important as effective thickness loss. Equivalent thickness loss for all three cases is increases almost linearly with the increase of DOP when DOP is smaller than approximately 75% [10]. The trend is especially evident foe equivalent thickness loss for ultimate tensile strength. Equivalent thickness loss for tensile strength (that equals to average thickness loss at minimum cross section) is larger than that for other loading conditions; only for largest values of DOP it is equal to 1.44\(t_{e}\) that is specified for structural models The same observation has been made for plates under in-plane compression and bending [5] described above. Therefore, it is possible to ensure the structural integrity if the average thickness loss at the minimum cross section is within the allowable corrosion level specified in rules for uniformly corroded members [10]. Allowable value of DOP could be evaluated on the base of allowable thickness loss for uniform corrosion, equivalent thickness loss for the pitted plate, and Fig. 4.

![Diagram of average thickness loss](image)

**Fig. 4.** Diagram of average thickness loss \(t_{av}\) equivalent thickness loss under combination of compression and shear \((1.25t_{el})\) equivalent thickness loss for ultimate strength of structural models \((1.44t_{el})\) and equivalent thickness loss for tensile strength at minimum cross section \((t_{cl})\) versus degree of pitting (DOP) [10]

Analyzing progress of pitting corrosion as a function of DOP, it has appeared [10] that average thickness loss and standard deviation of the thickness loss vary with small scatter band, while large scatter band is observed for extreme values like maximum pit depth or average thickness loss at the minimum cross section. When average thickness loss exceeds about 2 mm for one side of plate, then DOP equals about 100%. After this stage the form of corrosion tends to a change from pitting corrosion to general corrosion.

The same authors [8] have investigated experimentally and analytically (FEM) strength of 4 point bent welded frames contained of web plate, face plate and shell (tensile load act on the face plate). Artificial pits were made over a separated areas of the web plate. Lowest strength had a frame with a band of pits close to the compressed shell, higher strength had the frame with a band of pits situated at the center of the web height, highest strength had the frame with pits close to tensed face plate. Pits situated at the center of the frame length (pure bending segment) more significantly reduced strength than that situated close to ends (high shear stress). It means that localization of pitting corrosion at the web plate surface is an additional factor influencing the strength of frame. Influence...
of this position of pitting corrosion on the frame strength for longer, slender frames is less pronounced than for short frames.

CONCLUSIONS

1. Uniform thickness loss does not influence the total elongation of specimens in tensile test. Pitting corrosion, even of small degree of pit intensity, very significantly reduce total elongation of the specimens. Pitting corrosion reduces the ultimate tensile strength of steels stronger than the uniform corrosion.

2. For tension and any combination of in-plane compression and bending, the ultimate strength of pitted plate is smaller than that of uniformly corroded plate with the same average thickness loss. There is a tendency for the strength reduction to increase with the as the pit diameter and depth is increased. Thus a prediction of the strength of pitted plates using the average thickness loss would lead to non-conservative results.

3. The equivalent thickness (t_e), defined as the thickness of uniformly corroded plate whose ultimate strength is the same as that of pitted plate, for tensile loading is smaller than for any combination of in-plane compression and bending. Therefore it can be applied for conservative prediction of strength of members subjected to each of the loading modes.

4. It is possible and convenient to analyze the ultimate strength of pitted structures as a function of degree of pitting (DOP – the ratio of the total pitted area to the entire area of the plate) instead as a function of the plate thickness loss.

5. Ultimate buckling strength of pitted plates and frames depends also of the position of the pitted areas and the type of pit distribution in every area.

Polish Maritime Research
The Ship Handling Research and Training Centre at Ilawa is owned by the Foundation for Safety of Navigation and Environment Protection, which is a joint venture between the Gdynia Maritime University, the Gdansk University of Technology and the City of Ilawa.

**Two main fields of activity of the Foundation are:**

- **Training on ship handling.** Since 1980 more than 2500 ship masters and pilots from 35 countries were trained at Ilawa Centre. The Foundation for Safety of Navigation and Environment Protection, being non-profit organisation is reinvesting all spare funds in new facilities and each year to the existing facilities new models and new training areas were added. Existing training models each year are also modernised, that's why at present the Centre represents a modern facility perfectly capable to perform training on ship handling of shipmasters, pilots and tug masters.

- **Research on ship's manoeuvrability.** Many experimental and theoretical research programmes covering different problems of manoeuvrability (including human effect, harbour and waterway design) are successfully realised at the Centre.

The Foundation possesses ISO 9001 quality certificate.

**Why training on ship handling?**

The safe handling of ships depends on many factors - on ship's manoeuvring characteristics, human factor (operator experience and skill, his behaviour in stressed situation, etc.), actual environmental conditions, and degree of water area restriction.

Results of analysis of CRG (collisions, rammings and groundings) casualties show that in one third of all the human error is involved, and the same amount of CRG casualties is attributed to the poor controllability of ships. Training on ship handling is largely recommended by IMO as one of the most effective method for improving the safety at sea. The goal of the above training is to gain theoretical and practical knowledge on ship handling in a wide number of different situations met in practice at sea.
